Abstract
As information technology progresses, computers of these days can access more information than in the past, and thereby the need to integrate many pieces of knowledge increases. This paper discusses the integration of declarative knowledge. More specifically, it discusses the construction of a coherent knowledge representation out of small pieces of knowledge using a background KB. The paper will cover several challenging issues arising in knowledge integration, our approach and future work.

One of the goals of AI is to build a comprehensive knowledge base incrementally by acquiring fragments of knowledge from multiple sources, probably by reading texts (fig. 1). The key facility in a system - apart from natural language processing, which is beyond the scope of this paper - is knowledge integration: the ability to combine fragments of knowledge into a coherent whole. Although some recent systems (Harrington & Clark 2007) (Yatskevich, Welty, & Murdock 2006) (Noy 2004) provided aspects of this facility, their main focus was on identifying coreferences among the snippets of knowledge. In contrast, in this paper, KI entails considerably more than coreference identification. A KI facility, such as the one we are developing, would have application for a variety of AI tasks, such as NLP, Knowledge Actuision, and computational models of human learning.

Challenges in KI
Fig. 2 shows an example of KI which combines two pieces of information about Blood Circulation. Background knowledge, in this case, about the concept, PUMPING, is used to improve the coherence of the combination. With the example, this section presents challenging issues of KI which received little attention in AI.

- **Maximizing coherence** Typically, multiple snippets of knowledge can be combined in many ways. A challenge in knowledge integration is finding the combination that maximizes coherence. While researchers have identified some of the factors that influence coherence, a complete theory has not emerged.

- **Semantic matching** Integrating multiple knowledge representations requires aligning them. The alignment process involves identifying semantically matched parts among the representations. This can be challenging because same information can be represented in different ways. For example, “Blood moves from the heart to the lung” and “A lung receives the blood from the heart” express the same meaning, though their formal representations would be different.

- **Implicit information** Humans are so good at filling in unspecified gaps in several pieces of knowledge that are related. One of the challenges to KI is to identify such unspecified information. For example, fig. 2 shows a causal relation between MOVEMENT of BLOOD in source1 and PUMPING of HEART in source2 (dashed line).

- **Granularity difference** A special case of previous two challenges is that representations could be different in the level of detail. For example, source2 uses HEART and LUNG as an origin and a destination of MOVEMENT of BLOOD, whereas background knowledge, PUMPING, encodes that FLUID moves from CHAMBER to CONDUIT (shaded parts of fig. 2). KI has to identify such granularity differences and combine the representations based on
A heart is a pump that pumps blood

Blood moves from the heart to the lung

Figure 2: Integration of two logical forms about Blood circulation. Background knowledge, Pumping, improves the coherence of the integration by revealing a causal relation between the input representations (dashed line). The bold lines in the resulting knowledge structure signify the representations in source 1 and source 2.

Our approach and algorithm

This section introduces an algorithm, KI (Algorithm1), to handle the challenges in Section 2. The algorithm consists of two steps: stitch and elaborate. In the stitch phase, two representations are combined using GRAPH-MATCH (Algorithm3), and in the elaboration phase, the combined result is further elaborated by a knowledge base (KB). The elaboration phase also uses GRAPH-MATCH. GRAPH-MATCH extends simple graph-matching (Algorithm2) in the following ways:

- **Demons** In simple graph-matching (Algorithm2), two triples are aligned if one subsumes the other. For example, (Animal has-part Limb) can be aligned with (Human has-part Leg) in that way. GRAPH-MATCH extends this alignment by considering not only subsumption relations but other types of alignment, such as resolution of granularity differences. More specifically, GRAPH-MATCH runs multiple demons, each of which looks for a specific pattern and combines the two representations if the pattern is found. If more than one demon is applicable, the algorithm branches to create all possible alignments. The next section describes the use of demons in more detail.

- **Use of beam** Reasoning in KI is uncertain, so the graph match algorithm maintains a beam of multiple states, each of which corresponds to a different way of integrating the representations. Because the beam size is limited, the algorithm requires an intelligent way of selecting beam elements which will be retained. Devising such a selection method is one of our future goals.

**Algorithm 1 (KI)** Top-level algorithm for KI. It first relates two input representations and then elaborates further the related representations using a background KB.

**Input**: \(G_1, G_2\) : input graphs

**KB**, a background KB

**Output**: combined knowledge representation

**Algorithm**

result1 ← Use GRAPH-MATCH to combine \(G_1\) and \(G_2\) (stitch phase)

result2 ← Use GRAPH-MATCH to combine result1 and a knowledge structure \(G_{KB}\) in \(KB\) (elaboration phase)

return result2

**Demons**

The demons introduced in this section are mainly aimed at handling granularity differences introduced in (Kim & Porter 2007). But, the use of demons can apply for other types of alignment in a framework of GRAPH-MATCH as well. We will explain each demon with a specific pattern that it looks for and an action that it executes. In this section, the Component Library (Barker, Porter, & Clark 2001) is used as our ontology.

**Subsumption-based alignment** This demon aligns two triples in a subsumption relation. This is a pattern used in simple graph-matching.
Algorithm 2 simple graph-matching (Variable names are shown in a slanted style)

**Input:** \(G_1, G_2\) : input graphs  
**Output:** combined knowledge representation  
**Algorithm**

node-pair-queue ← initial starting nodes from \(G_1\) and \(G_2\) that are aligned with each other  
while node-pair-queue is not empty do  
\((c_1, c_2)\) ← the top element in node-pair-queue  
for all triples, \(t_1\), adjacent to \(c_1\) in \(G_1\)  
find a triple in \(G_2\), \(t_2\), that \(t_1\) subsumes (or vice versa), and then add \((t_1, t_2)\) to mappings  
add to node-pair-queue a new node mapping from \(t_1\) and \(t_2\)  
end for  
end while

Join \(G_1\) and \(G_2\) based on mappings

Algorithm 3 (GRAPH-MATCH) This algorithm extends Algorithm 2. *Italic parts* are new steps added to Algorithm 2.

**Input:** \(G_1, G_2\) : input graphs  
**Output:** combined knowledge representation  
**Internal Data Structure**

State ::= \{node-pair-queue\}

**Algorithm**

node-pair-queue ← initial starting nodes from \(G_1\) and \(G_2\) that are aligned with each other  
create state \(S_1\) with node-pair-queue  
add \(S_1\) to beam  
for all states \(S\) in beam whose node-pair-queue is not empty do  
\((c_1, c_2)\) ← the top element in node-pair-queue of \(S\)  
for all triples, \(t_1\), adjacent to \(c_1\) in \(G_1\) do  
Each demon aligns \(t_1\) with \(G_2\) in its own way and then updates node-pair-queue  
create a new state, \(S_{\text{new}}\), with the updated node-pair-queue and add \(S_{\text{new}}\) into beam  
end for  
end for

Join \(G_1\) and \(G_2\) based on the mappings of the best state in beam

**X-onomy based alignment** This pattern generalizes the one used in subsumption-based alignment. During graph matching, the algorithm determines co-references among the entities and events mentioned in the graph. This can be challenging because the entities and events can differ in level of granularity. The algorithm uses a demon to handle this case. The pattern of this demon uses a relation, X-onomy. X-onomy is a general relation that includes all relations that involve hierarchy, such as has-part(partonomy), enclose, isa(taxonomy), etc.

**Example**

(before KI)  
Blood moves from the left ventricle in the heart to the body.  
(after KI)  
Blood moves from the left ventricle in the heart to the body.

The above demon can be transformed to another one that can align two triples whose heads and relations are taxonomically aligned with each other but tails are not aligned. This is a pattern in which (B X-onomy C) is ablated from X-onomy based demon. On detecting such pattern, this new demon aligns the partially-aligned triples by installing a X-onomy relation between the tails.
Replication-based alignment Another common case in granularity mismatch is when one representation contains many repetitions of a triple in the other.

Example (before KI)

Blood moves from the left ventricle to the body.

Example (after KI)

Blood moves from the left ventricle to the body.

The left ventricle is in Xonomy relation with the heart.

Generalization-based alignment In this case, several pieces of similar information can be generalized. For example, “A heart has a left atrium” and “A heart has a right atrium” can be generalized into “A heart has atria”.

Pattern (Template)

G1 and G2 has the subgraphs that can be aligned with the above template

Action
Align G1 with G2 through the template

Abstraction-based alignment In this case, two things that are consecutive temporally or spatially can be viewed as one thing. The pattern of this demon uses a relation, “lateral relation”, which connects concepts in the same level of detail (e.g. next-event, beside, etc.).

Pattern

G1 has (X r1 Y) and G2 has n repetition of (A r Bx) such that X and Y are in a subsumption relation with A and Bx respectively.

Action
Replicate the relevant parts in G1 n times, and X, Y1, ..., Yn are mapped with A, B1, ..., Bn.
G1 and G2 has the subgraphs that can be aligned with the above pattern

**Pattern**

(template)

\[
\begin{array}{c}
\text{x} \\
\text{r1} \\
\text{x} \\
\text{Y} \\
\text{r2} \\
\text{x}
\end{array}
\]

**Action**

Align G1 with G2 through the template

**Example**

(before KI)

\[
\begin{array}{c}
\text{Heart} \\
\text{origin} \\
\text{Move} \\
\text{Blood} \\
\text{Lung} \\
\text{object} \\
\text{Destination}
\end{array}
\]

Blood moves from the heart to the lung

(after KI)

\[
\begin{array}{c}
\text{Heart} \\
\text{origin} \\
\text{subevent} \\
\text{Move} \\
\text{Body} \\
\text{destination} \\
\text{Move} \\
\text{Lung} \\
\text{subevent} \\
\text{Destination} \\
\text{Move}
\end{array}
\]

Blood moves from the heart to the lung and from the lung to the body

(For the limitation of space, Blood is not encoded)

Note that if only **Subsumption-based alignment** is used, the algorithm becomes simple graph-matching (algorithm2).

**Application to Learning-by-Reading**

The goal of Learning-by-Reading project (Barker et al. 2007) is to develop a system that reads a scientific text and generates a formal representation of it. The role of KI in the system is to produce a text-level representation by combining together logical forms of individual sentences generated by natural language software. We plan an experiment to measure the contribution of KI to improving the coherence and cohesiveness of the final representation. In particular, connectivity will be measured among the logical forms, since the much connected representations are typically coherent and cohesive (Zadrozny & Jensen 1991). The connectivity can be calculated by the ratio of the associated parts of the logical forms to the sum of the sizes of them. Since connectivity alone is not enough, the correctness of integration made by the algorithms will be evaluated by human judges.

**Related Work**

KI has been a key component in learning, knowledge acquisition and natural language systems, although it has not been named as KI in many of these systems (Harrington & Clark 2007) (Yatskevich, Welty, & Murdock 2006) (Noy 2004) (Cullingford 1978).

One closely related area attempts to build a large-scale common-sense KB by reading texts in the Internet (Harrington & Clark 2007) (Yatskevich, Welty, & Murdock 2006). These systems typically focus on identifying corefered entities. Ontology merging (Noy 2004) is similar to KI in that both aim at aligning two different representations. However, ontology merging often takes input representations written in different KR languages, whereas KI in this paper assumes the same underlying language.
