Abstract
As information technology progresses, computers of these days can access more information than in the past, and thereby the need to integrate many pieces of knowledge increases. This paper discusses the integration of declarative knowledge. More specifically, it discusses the construction of a coherent knowledge representation out of small pieces of knowledge using a background KB. The paper will cover several challenging issues arising in knowledge integration, our approach and future work.

Challenges in KI

One of the goals of AI is to build a comprehensive knowledge base incrementally by acquiring fragments of knowledge from multiple sources, probably by reading texts(fig. 1). The key facility in a system - apart from natural language processing, which is beyond the scope of this paper - is knowledge integration: the ability to combine fragments of knowledge into a coherent whole. Although some recent systems (Harrington & Clark 2007) (Yatskevich, Welty, & Murdock 2006) (Noy 2004) provided aspects of this facility, their main focus was on identifying co-references among the snippets of knowledge. In contrast, in this paper, KI entails considerably more than coreference identification. A KI facility, such as the one we are developing, would have application for a variety of AI tasks, such as NLP, Knowledge Actuisition, and computational models of human learning.

○ Maximizing coherence Typically, multiple snippets of knowledge can be combined in many ways. A challenge in knowledge integration is finding the combination that maximizes coherence. While researchers have identified some of the factors that influence coherence, a complete theory has not emerged.

○ Semantic matching Integrating multiple knowledge representations requires aligning them. The alignment process involves identifying semantically matched parts among the representations. This can be challenging because same information can be represented in different ways. For example, “Blood moves from the heart to the lung” and “A lung receives the blood from the heart” express the same meaning, though their formal representations would be different.

○ Implicit information Humans are so good at filling in unspecified gaps in several pieces of knowledge that are related. One of the challenges to KI is to identify such unspecified information. For example, fig. 2 shows a causal relation between MOVement of BLOOD in source1 and PUMPING of HEART in source2 (dashed line).

○ Granularity difference A special case of previous two challenges is that representations could be different in the level of detail. For example, source2 uses HEART and LUNG as an origin and a destination of MOVement of BLOOD, whereas background knowledge, PUMPING, encodes that FLUID moves from CHAMBER to CONDUIT (shaded parts of fig. 2). KI has to identify such granularity differences and combine the representations based on...
A heart is a pump that pumps blood. Blood moves from the heart to the lung.

The demons introduced in this section are mainly aimed at handling granularity differences introduced in (Kim & Porter 2007). But, the use of demons can apply for other types of alignment in a framework of GRAPH-MATCH as well. We will explain each demon with a specific pattern that it looks for and an action that it executes. In this section, the Component Library (Barker, Porter, & Clark 2001) is used as our ontology.

**Demons**

The demons introduced in this section are mainly aimed at handling granularity differences introduced in (Kim & Porter 2007). But, the use of demons can apply for other types of alignment in a framework of GRAPH-MATCH as well. We will explain each demon with a specific pattern that it looks for and an action that it executes. In this section, the Component Library (Barker, Porter, & Clark 2001) is used as our ontology.

**Subsumption-based alignment** This demon aligns two triples in a subsumption relation. This is a pattern used in simple graph-matching.
Algorithm 2 simple graph-matching (Variable names are shown in a slanted style)

Input: $G_1, G_2$: input graphs
Output: combined knowledge representation

Algorithm

\[
\text{node-pair-queue} \leftarrow \text{initial starting nodes from } G_1 \text{ and } G_2 \text{ that are aligned with each other}
\]

while node-pair-queue is not empty do

(c1, c2) \leftarrow \text{the top element in node-pair-queue}

for all triples, $t_1$, adjacent to $c_1$ in $G_1$ do

find a triple in $G_2$, $t_2$, that $t_1$ subsumes (or vice versa), and then add ($t_1$, $t_2$) to mappings

add to node-pair-queue a new node mapping from $t_1$ and $t_2$

end for

end while

Join $G_1$ and $G_2$ based on mappings

Algorithm 3 (GRAPH-MATCH) This algorithm extends Algorithm 2. Italic parts are new steps added to Algorithm 2.

Input: $G_1, G_2$: input graphs
Output: combined knowledge representation

Internal Data Structure

State ::= {node-pair-queue}

Algorithm

\[
\text{node-pair-queue} \leftarrow \text{initial starting nodes from } G_1 \text{ and } G_2 \text{ that are aligned with each other}
\]

create state $S_1$ with node-pair-queue

add $S_1$ to beam

for all states $S$ in beam whose node-pair-queue is not empty do

(c1, c2) \leftarrow \text{the top element in node-pair-queue of } S

for all triples, $t_1$, adjacent to $c_1$ in $G_1$ do

Each demon aligns $t_1$ with $G_2$ in its own way and then updates node-pair-queue.

Create a new state, $S_{\text{new}}$, with the updated node-pair-queue and add $S_{\text{new}}$ into beam

end for

If beam contains more states than the threshold, select the top $N$ states

end for

Join $G_1$ and $G_2$ based on the mappings of the best state in beam

**X-onomy based alignment** This pattern generalizes the one used in subsumption-based alignment. During graph matching, the algorithm determines co-references among the entities and events mentioned in the graph. This can be challenging because the entities and events can differ in level of granularity. The algorithm uses a demon to handle this case. The pattern of this demon uses a relation, X-onomy. X-onomy is a general relation that includes all relations that involve hierarchy, such as has-part(partonomy), enclose, isa(taxonomy), etc.

**Pattern**

\[
\begin{array}{ccc}
X & \xrightarrow{r_1} & Y \\
A & \xrightarrow{r_2} & B \\
\end{array}
\]

$G_1$ has ($X \ x r_1 \ y$) and $G_2$ has ($A \ x r_2 \ B$) such that $X$, $r_1$, $Y$ are in a subsumption relation with $A$, $r_2$, $B$ respectively.

**Action**

$X$ and $Y$ are aligned with $A$ and $B$ respectively.

**Example**

- **Before KI**
  - A pump has a chamber.
  - A heart has atria.

- **After KI**
  - Blood moves from the left ventricle in the heart to the body.

The above demon can be transformed to another one that can align two triples whose heads and relations are taxonomically aligned with each other but tails are not aligned. This is a pattern in which ($B$ X-onomy $C$) is ablated from X-onomy based demon. On detecting such pattern, this new demon aligns the partially-aligned triples by installing a X-onomy relation between the tails.
Pattern

\[ X \xrightarrow{r_1} Y \quad A \xrightarrow{r_2} B \]

G1 has (X r1 Y) and G2 has (A r2 B) such that X and r1 are in a subsumption relation with A, r2 respectively but, Y is not with B.

**Action**

1) X is aligned with A
2) Add a new triple (Y X-onomy B) in the combined representation

---

**Example**

(before KI)

```
Body
destination
Move
Left-Ventricle
```

Blood moves from the left ventricle to the body.

(after KI)

```
Body
destination
Move
Left-Ventricle
```

Blood moves from the left ventricle to the body.

The left ventricle is in X-onomy relation with the heart.

---

**Replication-based alignment** Another common case in granularity mismatch is when one representation contains many repetitions of a triple in the other.

Pattern

\[ X \xrightarrow{r} Y \quad A \xrightarrow{r} B_1 \ldots \xrightarrow{r} B_n \]

G1 has (X r1 Y) and G2 has n repetition of (A r Bx) such that X and Y are in a subsumption relation with A and Bx respectively.

**Action**

Replicate the relevant parts in G1 n times, and X, Y1, ..., Yn are mapped with A, B1, ..., Bn.

---

**Generalization-based alignment** In this case, several pieces of similar information can be generalized. For example, “A heart has a left atrium” and “A heart has a right atrium” can be generalized into “A heart has atria.”

Pattern

(Template)

\[ X \xrightarrow{r} Y \quad X-onomy \]

G1 and G2 has the subgraphs that can be aligned with the above template

**Action**

Align G1 with G2 through the template

---

**Abstraction-based alignment** In this case, two things that are consecutive temporally or spatially can be viewed as one thing. The pattern of this demon uses a relation, “lateral relation”, which connects concepts in the same level of detail (e.g. next-event, beside, etc.).
G1 and G2 has the subgraphs that can be aligned with the above pattern:

**Pattern**

- **Action**

Align G1 with G2 through the template (before KI)

Example

- Blood moves from the heart to the lung
- Blood moves from the heart to the body
- Blood moves from the heart to the lung and from the lung to the body

(For the limitation of space, Blood is not encoded)

Note that if only Subsumption-based alignment is used, the algorithm becomes simple graph-matching (algorithm2).

**Application to Learning-by-Reading**

The goal of Learning-by-Reading project (Barker et al. 2007) is to develop a system that reads a scientific text and generates a formal representation of it. The role of KI in the system is to produce a text-level representation by combining together logical forms of individual sentences generated by natural language software. We plan an experiment to measure the contribution of KI to improving the coherence and cohesiveness of the final representation. In particular, connectivity will be measured among the logical forms, since the much connected representations are typically coherent and cohesive (Zadrozny & Jensen 1991). The connectivity can be calculated by the ratio of the associated parts of the logical forms to the sum of the sizes of them. Since connectivity alone is not enough, the correctness of integration made by the algorithms will be evaluated by human judges.

**Related Work**

KI has been a key component in learning, knowledge acquisition and natural language systems, although it has not been named as KI in many of these systems (Harrington & Clark 2007) (Yatskevich, Welty, & Murdock 2006) (Noy 2004) (Cullingford 1978).

One closely related area attempts to build a large-scale common-sense KB by reading texts in the Internet (Harrington & Clark 2007) (Yatskevich, Welty, & Murdock 2006). These systems typically focus on identifying corefered entities. Ontology merging (Noy 2004) is similar to KI in that both aim at aligning two different representations. However, ontology merging often takes input representations written in different KR languages, whereas KI in this paper assumes the same underlying language.
