SafeStore: A Durable and Practical Storage System

Ramakrishna Kotla, Lorenzo Alvisi, and Mike Dahlin The University of Texas at Austin

Abstract

This paper presents SafeStore, a distributed storage system designed to maintain long-term data durability despite conventional hardware and software faults, environmental disruptions, and administrative failures caused by human error or malice. The architecture of SafeStore is based on fault isolation, which Safe-Store applies aggressively along administrative, physical, and temporal dimensions by spreading data across autonomous storage service providers (SSPs). However, current storage interfaces provided by SSPs are not designed for high end-to-end durability. In this paper, we propose a new storage system architecture that (1) spreads data efficiently across autonomous SSPs using informed hierarchical erasure coding that, for a given replication cost, provides several additional 9's of durability over what can be achieved with existing black-box SSP interfaces, (2) performs an efficient end-to-end audit of SSPs to detect data loss that, for a 20% cost increase, improves data durability by two 9's by reducing MTTR, and (3) offers durable storage with cost, performance, and availability competitive with traditional storage systems. We instantiate and evaluate these ideas by building a SafeStore-based file system with an NFSlike interface.

1 Introduction

The design of storage systems that provide data durability on the time scale of decades is an increasingly important challenge as more valuable information is stored digitally [10, 31, 57]. For example, data from the National Archives and Records Administration indicate that 93% of companies go bankrupt within a year if they lose their data center in some disaster [5], and a growing number of government laws [8, 22] mandate multiyear periods of data retention for many types of information [12, 50].

Against a backdrop in which over 34% of companies fail to test their tape backups [6] and over 40% of in-

dividuals do not back up their data at all [29], multidecade scale durable storage raises two technical challenges. First, there exist a broad range of threats to data durability including media failures [51, 60, 67], software bugs [52, 68], malware [18, 63], user error [50, 59], administrator error [39, 48], organizational failures [24, 28], malicious insiders [27, 32], and natural disasters on the scale of buildings [7] or geographic regions [11]. Requiring robustness on the scale of decades magnifies them all: threats that could otherwise be considered negligible must now be addressed. Second, such a system has to be practical with cost, performance, and availability competitive with traditional systems.

Storage outsourcing is emerging as a popular approach to address some of these challenges [41]. By entrusting storage management to a Storage Service Provider (SSP), where "economies of scale" can minimize hardware and administrative costs, individual users and small to medium-sized businesses seek costeffective professional system management and peace of mind vis-a-vis both conventional media failures and catastrophic events.

Unfortunately, relying on an SSP is no panacea for long-term data integrity. SSPs face the same list of hard problems outlined above and as a result even brandname ones [9, 14] can still lose data. To make matters worse, clients often become aware of such losses only after it is too late. This opaqueness is a symptom of a fundamental problem: SSPs are separate administrative entities and the internal details of their operation may not be known by data owners. While most SSPs may be highly competent and follow best practices punctiliously, some may not. By entrusting their data to back-box SSPs, data owners may free themselves from the daily worries of storage management, but they also relinquish ultimate control over the fate of their data. In short, while SSPs are an economically attractive response to the costs and complexity of long-term data storage, they do not offer their clients any end-to-end guarantees on data durability, which we define as the probability that a specific data object will not be lost or corrupted over a given time period.

Aggressive isolation for durability. SafeStore stores data redundantly across multiple SSPs and leverages diversity across SSPs to prevent permanent data loss caused by isolated administrator errors, software bugs, insider attacks, bankruptcy, or natural catastrophes. With respect to data stored at each SSP, SafeStore employs a "trust but verify" approach: it does not interfere with the policies used within each SSP to maintain data integrity, but it provides an *audit* interface so that data owner retain end-to-end control over data integrity. The audit mechanism can quickly detect data loss and trigger data recovery from redundant storage before additional faults result in unrecoverable loss. Finally, to guard data stored at SSPs against faults at the data owner site (e.g. operator errors, software bugs, and malware attacks), SafeStore restricts the interface to provide temporal isolation between clients and SSPs so that the latter export the abstraction of write-once-read-many storage.

Making aggressive isolation practical. SafeStore introduces an efficient storage interface to reduce network bandwidth and storage cost using an informed hierarchical erasure coding scheme, that, when applied across and within SSPs, can achieve near-optimal durability. SafeStore SSPs expose redundant encoding options to allow the system to efficiently divide storage redundancies across and within SSPs. Additionally, SafeStore limits the cost of implementing its "trust but verify" policy through an audit protocol that shifts most of the processing to the audited SSPs and encourages them proactively measure and report any data loss they experience. Dishonest SSPs are quickly caught with high probability and at little cost to the auditor using probabilistic spot checks. Finally, to reduce the bandwidth, performance, and availability costs of implementing geographic and administrative isolation, SafeStore implements a twolevel storage architecture where a local server (possibly running on the client machine) is used as a soft-state cache, and if the local server crashes, SafeStore limits down-time by quickly recovering the critical meta data from the remote SSPs while the actual data is being recovered in the background.

Contributions. The contribution of this paper is a highly durable storage architecture that uses a new replication interface to distribute data efficiently across diverse set of SSPs and an effective audit protocol to check data integrity. We demonstrate that this approach can provide high durability in a way that is practical and economically viable with cost, availability, and performance competitive with traditional systems. We demonstrate that the systems we demonstrate the systems.

strate these ideas by building and evaluating SSFS, an NFS-based SafeStore storage system. Overall, we show that SafeStore provides an economical alternative to realize multi-decade scale durable storage for individuals and small-to-medium sized businesses with limited resources. Note that although we focus our attention on outsourced SSPs, the SafeStore architecture could also be applied internally by large enterprises that maintain multiple isolated data centers.

2 Architecture and Design Principles

The main goal of SafeStore is to provide extremely durable storage over many years or decades.

2.1 Threat model

Over such long time periods, even relatively rare events can affect data durability, so we must consider broad range of threats along multiple dimensions—physical, administrative, and software.

Physical faults: Physical faults causing data loss include disk media faults [35, 67], theft [23], fire [7], and wider geographical catastrophes [11]. These faults can result in data loss at a single node or spanning multiple nodes at a site or in a region.

Administrative and client-side faults: Accidental misconfiguration by system administrators [39, 48], deliberate insider sabotage [27, 32], or business failures leading to bankruptcy [24] can lead to data corruption or loss. Clients can also delete data accidentally by, for example, executing "rm -r *". Administrator and client faults can be particularly devastating because they can affect replicas across otherwise isolated subsystems. For instance [27], a system administrator not only deleted data but also stole the only backup tape after he was fired, resulting in financial damages in excess of \$10 million and layoff of 80 employees.

Software faults: Software bugs [52, 68] in file systems, viruses [18], worms [63], and Trojan horses can delete or corrupt data. A vivid example of threats due to malware is the recent phenomenon of ransomware [20] where an attacker encrypts a user's data and withholds the encryption key until a ransom is paid.

Of course, any of the listed faults may occur rarely. But at the scale of decades, it becomes risky to assume that no rare events will occur. It is important to note that some of these failures [7, 51, 60] are often correlated resulting in simultaneous data loss at multiple nodes while others [52] are more likely to occur independently.

Limitations of existing practice. Most existing approaches to data storage face two problems that are particularly acute in our target environments of individuals

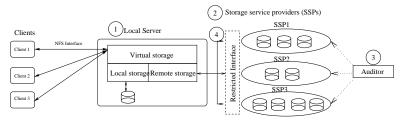

Fig. 1: SafeStore architecture

and small/medium businesses: (1) they depend too heavily on the operator or (2) they provide insufficient fault isolation in at least some dimensions.

For example, traditional removable-media-basedsystems (e.g., tape, DVD-R) systems are labor intensive, which hurts durability in the target environments because users frequently fail to back their data up, fail to transport media off-site, or commit errors in the backup/restore process [25]. The relatively high risk of robot and media failures [3] and slow mean time to recover [44] are also limitations.

Similarly, although on-site disk-based [4, 16] backup systems speed backup/recovery, use reliable media compared to tapes, and even isolate client failures by maintaining multiple versions of data, they are vulnerable to physical site, administrative, and software failures.

Finally, network storage service providers (SSPs) [1, 2, 15, 21] are a promising alternative as they provide geographical and administrative isolation from users and they ride the technology trend of falling network and hardware costs to reduce the data-owner's effort. But they are still vulnerable to administrative failures at the service providers [9], organizational failures (e.g., bankruptcy [24, 41]), and operator errors [28]. They thus fail to fully meet the challenges of a durable storage system. We do, however, make use of SSPs as a component of SafeStore.

2.2 SafeStore architecture

As shown in Figure 1, SafeStore uses the following design principles to provide high durability by tolerating the broad range of threats outlined above while keeping the architecture practical, with cost, performance, and availability competitive with traditional systems.

Efficiency via 2-level architecture. SafeStore uses a two-level architecture in which the data owner's *local* server (① in Figure 1) acts as a cache and write buffer while durable storage is provided by multiple remote storage service providers SSPs ② The local server could be running on the client's machine or a different machine. This division of labor has two consequences. First, performance, availability, and network cost are

improved because most accesses are served locally; we show this is crucial in Section 3. Second, management cost is improved because the requirements on the local system are limited (local storage is soft state, so local failures have limited consequences) and critical management challenges are shifted to the SSPs, which can have excellent economies of scale for managing large data storage systems [1, 26, 41].

Aggressive isolation for durability. We apply the principle of aggressive isolation in order to protect data from the broad range of threats described above.

- Autonomous SSPs: SafeStore stores data redundantly across multiple autonomous SSPs (②in Figure 1). Diverse SSPs are chosen to minimize the likelihood of common-mode failures across SSPs. For example, SSPs can be external commercial service providers [1, 2, 15, 21], that are geographically distributed, run by different companies, and based on different software stacks. Although we focus on *out-sourced* SSPs, large organizations can use our architecture with *in-sourced* storage across autonomous entities within their organization (e.g., different campuses in a university system.)
- *Audit:* Aggressive isolation alone is not enough to provide high durability as data fragment failures accumulate over time. On the contrary, aggressive isolation can adversely affect data durability because the data owner has little ability to enforce or monitor the SSPs' internal design or operation to ensure that SSPs follow best practices. We provide an end-to-end audit interface (③ in Figure 1) to detect data loss and thereby bound mean time to recover (MTTR), which in turn increases mean time to data loss (MTTDL). In Section 4 we describe our audit interface and show how audits limit the damage that poorly-run SSPs can inflict on overall durability.
- *Restricted interface:* SafeStore must minimize the likelihood that erroneous operation of one subsystem compromises the integrity of another [46]. In particular, because SSPs all interact with the local server, we must restrict that interface. For example, we must protect against careless users, malicious insiders, or

devious malware at the clients or local server that mistakenly delete or modify data. SafeStore's restricted SSP interface ④ provides temporal isolation via the abstraction of versioned write-once-read-many storage so that a future error cannot damage existing data.

Making isolation practical. Although durability is our primary goal, the architecture must still be economically viable.

- *Efficient data replication:* The SafeStore architecture defines a new interface that allows the local server to realize near-optimal durability using *informed hierarchical erasure coding* mechanism, where SSPs expose internal redundancy. Our interface does not restrict SSP's autonomy in choosing internal storage organization (replication mechanism, redundancy level, hardware platform, software stack, administrative policies, geographic location, etc.) Section 3 shows that our new interface and replication mechanism provides orders of magnitude better durability than *oblivious hierarchical encoding* based systems using existing black-box based interfaces [1, 2, 21].
- *Efficient audit mechanism:* To make audits of SSPs practical, we use a novel audit protocol that, like real world financial audits, uses self-reporting whereby auditor offloads most of the audit work to the auditee (SSP) in order to reduce the overall system resources required for audits. However, our audit takes the form of a challenge-response protocol with occasional spot-checks that ensure that an auditee that generates improper responses is quickly discovered and that such a discovery is associated with a cryptographic proof of misbehavior [30].
- Other optimizations: We use several optimizations to reduce overhead and downtime in order to make system practical and economically viable. First, we use a fast recovery mechanism to quickly recover from data loss at a local server where the local server comes online as soon as the meta-data is recovered from remote SSPs even while data recovery is going on in the background. Second, we use block level versioning to reduce storage and network overhead involved in maintaining multiple versions of files.

2.3 Economic viability

In this section, we consider the economic viability of our storage system architecture in two different settings, outsourced storage using commercial SSPs and federated storage using in-house but autonomous SSPs, and calibrate the costs by comparing with a less-durable local storage system.

We consider three components to storage cost: hardware resources, administration, and—for outsourced

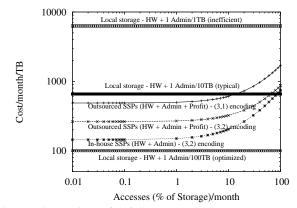

Fig. 2: Comparison of SafeStore cost v. accesses to remote storage (as a percentage of straw-man Standalone local storage) varies.

storage-profit. Table 1 summarizes our basic assumptions for a straw-man Standalone local storage system and for the local owner and SSP parts of a SafeStore system. In column B, we estimate the raw hardware and administrative costs that might be paid by an in-house SSP. We base our storage hardware costs on estimated full-system 5-year total cost of ownership (TCO) costs in 2006 for large-scale internet services such as Internet Archive [26]. Note that using the same storage cost for a large-scale, specialized SSP and for smaller data owners and Standalone systems is conservative in that it may overstate the relative additional cost of adding SSPs. For network resources, we base our costs on published rates in 2006 [17]. For administrative costs, we use Gray's estimate that highly efficient internet services require about 1 administrator to manage 100TB while smaller enterprises are typically closer to one administrator per 10TB but can range from one per 1TB to 1 per 100TB [49] (Gray notes, "But the real cost of storage is management" [49]). Note that we assume that by transforming local storage into a soft-state cache, Safe-Store simplifies local storage administration. We therefore estimate local hardware and administrative costs at 1 admin per 100TB.

In Figure 2, the storage cost of in-house SSP includes SafeStore's hardware (cpu, storage, network) and administrative costs. We also plot the straw-man local storage system with 1, 10, or 100 TB per administrator. The outsourced SSP lines show SafeStore costs assuming SSPs prices include a profit by using Amazon's S3 storage service pricing. Three points stand out. First, additional replication to SSPs increases cost (as inter-SSP data encoding, as discussed in section 3, is raised from (3,2) to (3,1)), and the network cost rises rapidly as the remote access rate increases. These factors motivate SafeStore's architectural decisions to (1) use ef-

	Standalone	SafeStore In-house	SafeStore SSP (Cost+Profit)
Storage	\$30/TB/month [26]	\$30/TB/month [26]	\$150/TB/month [1]
Network	NA	\$200/TB [17]	\$200/TB [1]
Admin	1 admin/[1,10,100]TB ([inefficient,typical,optimized]) [49]	1 admin/100TB [49]	Included [1]

Table 1: System cost assumptions. Note that a *Standalone* system makes no provision for isolated backup and is used for cost comparison only.

ficient encoding and (2) minimize network traffic with a large local cache that fully replicates all stored state. Second, when SSPs are able to exploit economies of scale to reduce administrative costs below those of their customers, SafeStore can reduce overall system costs even when compared to a less-durable Standalone localstorage-only system. Third, even for customers with highly-optimized administrative costs, as long as most requests are filtered by the local cache, SafeStore imposes relatively modest additional costs that may be acceptable if it succeeds in improving durability.

The rest of the paper is organized as follows. First, in Section 3 we present and and evaluate our novel *informed hierarchical erasure coding* mechanism. In Section 4, we address SafeStore's audit protocol. Later, in Section 5 we describe the SafeStore interfaces and implementation. We evaluate the prototype in Section 6. Finally, we present the related work in Section 7.

3 Data replication interface

This section describes a new replication interface to achieve near-optimal data durability while limiting the internal details exposed by SSPs, controlling replication cost, and maximizing fault isolation.

SafeStore uses hierarchical encoding comprising inter-SSP and intra-SSP redundancy: First, it stores data redundantly across different SSPs, and then each SSP internally replicates data entrusted to it as it sees fit. Hierarchical encoding is the natural way to replicate data in our setting as it tries to maximize fault-isolation across SSPs while allowing SSP's autonomy in choosing an appropriate internal data replication mechanism. Different replication mechanisms such as erasure coding [55], RAID [35], or full replication can be used to store data redundantly at inter-SSP and intra-SSP levels (any replication mechanism can be viewed as some form of (k,l) encoding [65] from durability perspective, where 1 out of k encoded fragments are required to reconstruct data). However, it requires proper balance between inter-SSP and intra-SSP redundancies to maximize end-end durability for a fixed storage overhead. For example, consider a system willing to pay an overall 6x redundancy cost using 3 SSPs with 8 nodes each. If, for example, each SSP only provides the option of (8,2) intra-SSP encoding, then we can use at most (3,2) inter-SSP encoding. This combination gives gives 4 9's less durability for the same overhead compared to a system that uses (3,1) encoding at the inter-SSP level and (8,4) encoding at the intra-SSP level at all the SSPs.

3.1 Model

The overall storage overhead to store a data object is $(n_0/m_0 + n_1/m_1 + ... n_{k-1}/m_{k-1})/l$, when a data object is hierarchically encoded using (k, l) erasure coding across k SSPs, and SSPs 0 through k-1 internally use erasure codings (n_0, m_0) , $(n_1, m_1), \dots, (n_{k-1}, m_{k-1})$, respectively. We assume that the number of SSPs(k) is fixed and a data object is (possibly redundantly) stored at all SSPs. We do not allow varying k as it requires additional internal information about various SSPs (MTTF of nodes, number of nodes, etc.) which may not be available in order to choose optimal set of k nodes. Instead, we tackle the problem of finding optimal distribution of inter-SSP and intra-SSP redundancies for a fixed k. The end-to-end data durability can be estimated as a function of these variables using a simple analytical model, detailed in Appendix A of our extended report [45], that considers two classes of faults. Node faults (e.g. physical faults like sector failures, disk crashes, etc.) occur within an SSP and affect just one fragment of an encoded object stored at the SSP. SSP faults (e.g., administrator errors, organizational failures, geographical failures, etc.) are instead simultaneous or nearsimultaneous failures that take out all fragments across which an object is stored within an SSP. To illustrate the approach, we consider a baseline system consisting of 3 SSPs with 8 nodes each. We use a baseline MTTDL of 10 years due to invidual node faults and 100 years for SSP failures and assume both are independent and identically distributed. We use MTTR of data of 2 days (e.g. to detect and replace a faulty disk) for node faults and 10 days for SSP failures. We use the probability of data loss of an object during a 10 year period to characterize durability because expressing end-to-end durability as MTTDL can be misleading [35] (although MTTDL can be easily computed from the probability of data loss as shown in our report [45]). Later, we change the distribution of nodes across SSPs, MTTDL and MTTR of node failures within SSPs, to model diverse SSPs. The conclusions that we draw here are general and not specific

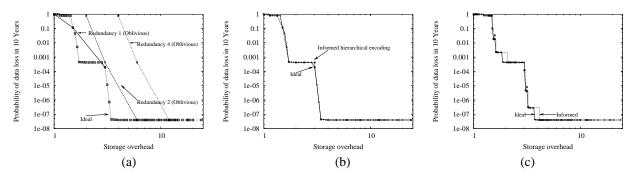

Fig. 3: (a) Durability with Black-box interface with fixed intra-SSP redundancy (b) Informed hierarchical encoding (c) Informed hierarchical encoding with non-uniform distribution

to this setup; we find similar trends when we change the total number of nodes, as well as MTTDL and MTTR of correlated *SSP faults*.

3.2 Informed hierarchical encoding

A client can maximize end-to-end durability if it can control both intra-SSP and inter-SSP redundancies. However, current black-box storage interfaces exported by commercial outsourced SSPs [1, 2, 21] do not allow clients to change intra-SSP redundancies. With such a black-box interface, clients perform oblivious hierarchical encoding as they control only inter-SSP redundancy. Figure 3(a) plots the optimal durability achieved by an ideal system that has full control of inter-SSP and intra-SSP redundancy and a system using oblivious hierarchical encoding. The latter system has 3 lines for different fixed intra-SSP redundancies of 1, 2, and 4, where each line has 3 points for each of the 3 different inter-SSP encodings((3,1), (3,2) and (3,3)) that a client can choose with such a black-box interface. Two conclusions emerge. First, for a given storage overhead, the probability of data loss of an *ideal* system is often orders of magnitude lower than a system using oblivious hierarchical encoding, which therefore is several 9's short of optimal durability. Second, a system using oblivious hierarchical encoding often requires 2x-4x more storage than *ideal* to achieve the same durability.

To improve on this situation, SafeStore describes an interface that allows clients to realize near-optimal durability using *informed hierarchical encoding* by exercising additional control on intra-SSP redundancies. With this interface, each SSP exposes the set of redundancy factors that it is willing to support. For example, an SSP with 4 internal nodes can expose redundancy factors of 1 (no redundancy), 1.33, 2, and 4 corresponding, respectively, to the (4,4), (4,3), (4,2) and (4,1) encodings used internally.

Our approach to achieve near-optimal end-to-end durability is motivated by the stair-like shape of the curve tracking the durability of *ideal* as a function of storage overhead (Figure 3(a)). For a fixed storage overhead, there is a tradeoff between inter-SSP and intra-SSP redundancies, as a given overhead *O* can be expressed as $1/l \times (r_0 + r_1 + ..r_{k-1})$, when (k, l) encoding is used across *k* SSPs in the system with intra-SSP redundancies of r_0 to r_{k-1} (where $r_i = n_i/m_i$). Figure 3(a) shows that durability increases dramatically (moving down one step in the figure) when inter-SSP redundancy increases, but does not improve appreciably when additional storage is used to increase intra-SSP redundancy beyond a threshold that is close to but greater than 1. This observation is backed by mathematical analysis in the extended report [45].

Hence, we propose a heuristic biased in favor of spending storage to maximize inter-SSP redundancy as follows:

- First, for a given number k of SSPs, we maximize the inter-SSP redundancy factor by minimizing l. In particular, for each SSP i, we choose the minimum redundancy factor r'_i > 1 exposed by i, and we compute l as l = |(r'₀ + r'₁ + ...r'_{k-1})/O|.
- Next, we distribute the remaining overhead (O−1/l× (r'₀ + r'₁ + ..r'_{k-1})) among the SSPs to minimize the standard deviation of the intra-SSP redundancy factors r_i that are ultimately used by the different SSPs.

Figure 3(b) shows that this new approach, which we call *informed hierarchical coding*, achieves near optimal durability in a setting where three SSPs have the same number of nodes (8 each) and the same MTTDL and MTTR for internal node failures. These assumptions, however, may not hold in practice, as different SSPs are likely to have a different number of nodes, with different MTTDLs and MTTRs. Figure 3(c) shows the result of an experiment in which SSPs have a different sets of redundancy factors. We still use 24 nodes, but we distribute them non-uniformly (14, 7, 3) across the

SSPs: informed hierarchical encoding continues to provide near-optimal durability. This continues to be true even when there is a skew in MTTDL and MTTR (due to node failures) across SSPs. For instance, Figure 4 uses the same non-uniform node distribution of Figure 3(c), but the (MTTDL, MTTR) values for node failures now differ across SSPs—they are, respectively, (10 years, 2 days), (5 years, 3 days), and (3 years, 5 days). Note that, by assigning the worst (MTTDL, MTTR) for node failures to the SSP with least number of nodes, we are considering a worst-case scenario for informed hierarchical encoding.

These results are not surprising in light of our discussion of Figure 3(a): durability depends mainly on maximizing inter-SSP redundancy and it is only slightly affected by the internal data management of individual SSPs. In our extended technical report [45] we perform additional experiments that study the sensitivity of informed hierarchical encoding to changes in the total number of nodes used to store data across all SSPs and in MTTDL and MTTR for SSP failures: they all confirm the conclusion that a simple interface that allows SSPs to expose the redundancy factors they support is all it is needed to achieve, through our simple informed hierarchical encoding mechanism, near optimal durability.

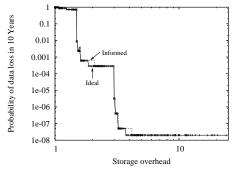

Fig. 4: Durability with different MTTDL and MTTR for node failures across SSPs

SSPs can provide such an interface as part of their SLA (service level agreement) and charge clients based on the redundancy factor they choose when they store a data object. The interface is designed to limit the amount of detail that an SSP must expose about the internal organization. For example, an SSP with 1000 servers each with 10 disks might only expose redundancy options (1.0, 1.1, 1.5, 2.0, 4.0, 10.0), revealing little about its architecture. Note that the proposed interface could allow a dishonest SSP to cheat the client by using less redundancy than advertised. The impact of such false advertising is limited by two factors: First, as observed above, our design is relatively insensitive to variations in

intra-SSP redundancy. Second, the end to end audit protocol described in the next section limits the worst-case damage any SSP can inflict.

4 Audit

We need an effective audit mechanism to quickly detect data losses at SSPs so that data can be recovered before multiple component failures resulting in unrecoverable loss. An SSP should safeguard the data entrusted to it by following best practices like monitoring hardware health [62], spreading coded data across drives and controllers [35] or geographically distributed data centers, periodically scanning and correcting latent errors [61], and quickly notifying a data owner of any lost data so that the owner can restore the data from other SSPs and maintain a desired replication level. However, the principle of isolation argues against blindly assuming SSPs are flawless system designers and operators for two reasons. First, SSPs are separate administrative entities, and their internal details of operation may not be verifiable by data owners. Second, given the imperfections of software [18, 52, 68], operators [39, 48], and hardware [35, 67], even name-brand SSPs may encounter unexpected issues and silently lose customer data [9, 14]. Auditing SSP data storage embodies the end-toend principle (in almost exactly the form it was first described) [58], and frequent auditing ensures a short Mean Time To Detect (MTTD) data loss, which helps limit worst-case Mean Time To Recover (MTTR). It is important to reduce MTTR in order to increase MTTDL as a good replication mechanism alone cannot improve MTTDL over a long time-duration spanning decades.

The technical challenge to auditing is to provide an end-to-end guarantee on data integrity while minimizing cost. These goals rule out simply reading stored data across the network as too expensive (see Figure 2) and, similarly, just retrieving a hash of the data as not providing an end-to-end guarantee (the SSP may be storing the hash not the data.). Furthermore, the audit protocol must work with data erasure-coded across SSPs, so a simple scheme that sends a challenge to multiple identical replicas and then compare the responses such as those in LOCKSS [46] and Samsara [37] do not work. We must therefore devise an inexpensive audit protocol despite the fact that no two replicas store the same data.

To reduce audit cost, SafeStore's audit protocol borrows a strategy from real-world audits: we push most of the work onto the auditee and ask the auditor to spot check the auditee's reports. Our reliance on selfreporting by SSPs drives two aspects of the protocol design. First, the protocol is believed to be *shortcut* *free*–audit responses from SSPs are guaranteed to embody end-to-end checks on data storage– under the assumption that collision resistant modification detection codes [47] exist. Second, the protocol is *externally verifiable* and *non-repudiable*—falsified SSP audit replies are quickly detected (with high probability) and deliberate falsifications can be proven to any third party.

4.1 Audit protocol

The audit protocol proceeds in three phases: (1) data storage, (2) routine audit, and (3) spot check. Note that the auditor may be co-located with or separate from the owner. For example, audit may be outsourced to an external auditor when data owners are offline for extended periods. To authorize SSPs to respond to auditor requests, the owner signs a certificate granting audit rights to the auditor's public key, and all requests from the auditor are authenticated against such a certificate (these authentication handshakes are omitted in the description below.) We describe the high level protocol here and detail it in the report [45].

Data storage. When an object is stored at an SSP, the SSP signs and returns to the data owner a *receipt* that includes the object ID, cryptographic hash of the data, and storage expiration time. The data owner in turn verifies that the signed hash matches the data it sent and that the receipt is not malformed with an incorrect id or expiration time. If the data and hash fail to match, the owner retries sending the write message (data could have been corrupted in the transmission); repeated failures indicate a malfunctioning SSP and generate a notification to the data owner. As we detail in Section 5, SSPs do not provide a delete interface, so the expiration time indicates when the SSP will garbage collect the data. The data owner collects such valid receipts, encodes them, and spreads them across SSPs for durable storage.

Routine audit. The auditor sends to an SSP a list of object IDs and a random challenge. The SSP computes a cryptographic hash on both the challenge and the data. The SSP sends a signed message to the auditor that includes the object IDs, the current time, the challenge, and the hash computed on the challenge and the data ($H(challenge + data_{objId})$). The auditor buffers the challenge responses if the messages are well-formed, where a message is considered to be well-formed if none of the following conditions are true: the signature does not match the message, the response with an unacceptably stale timestamp, the response with the wrong challenge, or the response indicates error code (e.g., he SSP detected data is corrupt via internal checks or the data has expired). If the auditor does not receive any response

from the SSP or if it receives a malformed message, the auditor notifies the data owner, and the data owner reconstructs the data via cached state or other SSPs and stores the lost fragment again. Of course, the owner may choose to switch SSPs before restoring the data and/or may extract penalties under their service level agreement (SLA) with the SSP, but such decisions are outside the scope of the protocol.

We conjecture that the audit response is shortcut free: an SSP must possess object's data to compute the correct hash. An honest SSP verifies the data integrity against the challenge-free hash stored at the creation time before sending a well-formed challenge response. If the integrity check fails (data is lost or corrupted) it sends the error code for lost data to the auditor. However, a dishonest SSP can choose to send a syntactically wellformed audit response with bogus hash value when the data is corrupted or lost. Note that the auditor just buffers well-formed messages and does not verify the integrity of the data objects covered by the audit in this phase. Yet, routine audits serve two key purposes. First, when performed against honest SSPs, they provide endto-end guarantees about the integrity of the data objects covered by the audit. Second, they force dishonest SSPs to produce a signed, non-repudiable statement about the integrity of the data objects covered by the audit.

Spot check. In each round, after it receives audit responses in the routine audit phase, the auditor randomly selects α % of the objects to be spot checked. The auditor then retrieves each object's data (via the owner's cache, via the SSP, or via other SSPs) and verifies that the cryptographic hash of the challenge and data matches the challenge response sent by the SSP in the routine audit phase. If there is a mismatch, the auditor informs the data owner about the mismatch and provides the signed audit response sent by the SSP. The data owner then can create an externally-verifiable proof of misbehavior (POM) [45] against the SSP: the receipt, the audit Note that SafeStore response, and the object's data. local server encrypts all data before storing it to SSPs, so this proof may be presented to third parties without leaking the plaintext object contents. Also, note that our protocol works with erasure coding as the auditor can reconstruct the data to be spot checked using redundant data stored at other SSPs.

4.2 Durability and cost

In this section we examine how the low-cost audit protocol limits the damage from faulty SSPs. The SafeStore protocol specifies that SSPs notify data owners immediately of any data loss that the SSP cannot internally recover so that the owner can restore the desired replica-

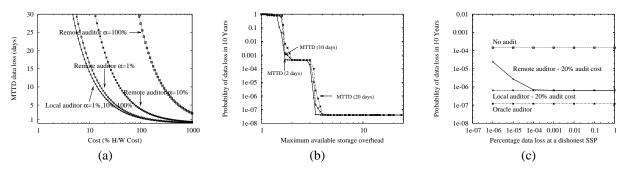

Fig. 5: (a) Time to detect SSP data loss via audit with varying amounts of resources dedicated to audit overhead assuming honest SSPs. (b) Durability with varying MTTD. (c) Impact on overall durability with a dishonest SSP. The audit cost model for hardware, storage, and network bandwidth are described in [45]

tion level using redundant data. Figures 3 and 4 illustrate the durability of our system when the SSPs follow the requirement and immediately report failures. As explained below, Figure 5-(a) and (b) show that SafeStore still provides excellent data durability with low audit cost, if a data owner is unlucky and selects a passive SSP that violates the immediate-notify requirement and waits for an audit of an object to report that it is missing. Figure 5-(c) shows that if a data owner is really unlucky and selects a dishonest SSP that first loses some of the owner's data and then lies when audited to try to conceal that fact, the owner's data is still very likely to emerge unscathed. We evaluate our audit protocol with 1TB of data stored redundantly across three SSPs with inter-SSP encoding of (3,1) (the extended report [45] has results with other encodings).

First, assume that SSPs are *passive* and wait for an audit to check data integrity. Because the protocol uses relatively cheap processing at the SSP to reduce data transfers across the wide area network, it is able to scan through the system's data relatively frequently without raising system costs too much. Figure 5-(a) plots the mean time to detect data loss (MTTD) at a passive SSP as a function of the cost of hardware resources (storage, network, and cpu) dedicated to auditing, expressed as a percentage of the cost of the system's total hardware resources as detailed in the caption. We also vary the fraction of objects that are spot checked in each audit round (α) for both the cases with local (co-located with the data owner) and remote (separated over WAN) auditors. We reach following conclusions: (1) As we increase the audit budget we can audit more frequently and the time to detect data loss falls rapidly. (2) audit costs with local and remote auditors is almost the same when α is less than 1%. (3) The audit cost with local auditor does not vary much with increasing α (as there is no additional network overhead in retrieving data from the local data owner) whereas the audit cost for the remote

auditor increases with increasing α (due to additional network overhead in retrieving data over the WAN). (4) Overall, if a system dedicates 20% of resources to auditing, we can detect a lost data block within a week (with a local or a remote auditor with $\alpha = 1\%$).

Given this information, Figure 5-(b) shows the modest impact on overall data durability of increasing the time to detect and correct such failures when we assume that all SSPs are *passive* and SafeStore relies on auditing rather than immediate self reporting to trigger data recovery.

Now consider the possibility of an SSP trying to brazen its way through an audit of data it has lost using a made-up value purporting to be the hash of the challenge and data. The audit protocol encourages rational SSPs that lose data to respond to audits honestly. In particular, we prove [45] that under reasonable assumptions about the penalty for an honest failure versus the penalty for generating a proof of misbehavior (POM), a rational SSP will maximize its utility [30] by faithfully executing the audit protocol as specified.

But suppose that through misconfiguration, malfunction, or malice, a node first loses data and then issues *dishonest* audit replies that claim that the node is storing a set of objects that it does not have. The spot check protocol ensures that if a node is missing even a small fraction of the objects, such cheating is quickly discovered with high probability. Furthermore, as that fraction increases, the time to detect falls rapidly. The intuition is simple: the probability of detecting a dishonest SSP in *k* audits is given by

$$p_k = 1 - (1 - p)^k$$

where p is the probability of detection in an audit, which is given by

$$p = \frac{\sum_{i=1}^{m} \binom{n}{i} \binom{N-n}{m-i}}{\binom{N}{m}}, \text{ (if } n \ge m)$$

WriteReceipt write(ID oid, byte data[], int64 size,			
int32 type, int64 expire);			
ReadReply read(ID oid, int64 size, int32 type)			
AttrReply get_attr(ID oid);			
TTLReceipt extend_expire(ID oid, int64 expire);			
Table 2: SSP storage interface			

$$p = \frac{\sum_{i=1}^{n} \binom{m}{i} \binom{N-m}{n-i}}{\binom{N}{n}}, \text{ (if } n < m)$$

where N is the total number of data blocks stored at an SSP, n is the number of blocks that are corrupted or lost and m is the number of blocks that are spot checked, $\alpha = (m/N) \times 100$.

Figure 5-(c) shows the overall impact on durability if a node that has lost a fraction of objects maximizes the time to detect these failures by generating dishonest audit replies. We fix the audit budget at 20% and measure the durability of SafeStore with local auditor (with α at 100%) as well as remote auditor (with α at 1%). We also plot the durability with oracle detector which detects the data loss immediately and triggers recovery. Note that the oracle detector line shows worse durability than the lines in Figure 5-(b) because (b) shows durability for a randomly selected 10-year period while (c) shows durability for a 10-year period that begins when one SSP has already lost data. Without auditing (no audit), there is significant risk of data loss reducing durability by three 9's compared to oracle detector. Using our audit protocol with remote auditor, the figure shows that a cheating SSP can introduce a non-negligible probability of smallscale data loss because it takes multiple audit rounds to detect the loss as it spot checks only 1% of data blocks. But that the probability of data loss falls quickly and comes closer to oracle detector line (with in one 9 of durability) as the amount of data at risk rises. Finally, with a local auditor, data loss is detected in one audit round independent of data loss percentage at the dishonest SSPs as a local auditor can spot check all the data. In the presence of dishonest SSPs, our audit protocol improves durability of our system by two 9's over a system with no audit at an additional audit cost of just 20%. We show in the extended report [45] that overall durability of our system improves with increasing audit budget and approaches the oracle detector line.

5 SSFS

We implement SSFS, a file system that embodies the SafeStore architecture and protocol. In this section, we first describe the SSP interface and our SSFS SSP implementation. Then, we describe SSFS's local server.

5.1 SSP

As Figure 1 shows, for long-term data retention SSFS local servers store data redundantly across administratively autonomous SSPs using erasure coding or full replication. SafeStore SSPs provide a simple yet carefully defined object store interface to local servers as shown in Table 2.

Two aspects of this interface are important. First, it provides non-repudiable receipts for writes and expiration extensions in order to support our spot-check-based audit protocol. Second, it provides *temporal isolation* to limit the data owner's ability to change data that is currently stored [46]. In particular, the SafeStore SSP protocol (1) gives each object an absolute expiration time and (2) allows a data owner to extend but not reduce an object's lifetime.

This interface supports what we expect to be a typical usage pattern in which an owner creates a ladder of backups at increasing granularity [59]. Suppose the owner wishes to maintain yearly backups for each year in the past 10 years, monthly backups for each month of the current year, weekly backups for the last four weeks, and daily backups for the last week. Using the local server's snapshot facility (see Section 5.2), on the last day of the year, the local server writes all current blocks that are not yet at the SSP with an expiration date 10-years into the future and also iterates across the most recent version of all remaining blocks and sends extend_expire requests with an expiration date 10-years into the future. Similarly, on the last day of each month, the local server writes all new blocks and extends the most recent version of all blocks; notice that blocks not modified during the current year may already have expiration times beyond the 1-year target, but these extensions will not reduce this time. Similarly, on the last day of each week, the local server writes new blocks and extends deadlines of the current version of blocks for a month. And every night, the local server writes new blocks and extends deadlines of the current version of all blocks for a week. Of course, SSPs ignore extend_expire requests that would shorten an object's expiration time.

SSP implementation. We have constructed a prototype SSFS SSP that supports all of the features described in this paper including the interface for servers and the interface for auditors. Internally, each SSP spreads data across a set nodes using erasure coding with a redundancy level specified for each data owner's account at account creation time.

For compatibility with legacy SSPs, we also implement a simplified SSP interface that allows data owners to store data to Amazon's S3 [1], which provides a simple non-versioned read/write/delete interface and which does not support our optimized audit protocol.

Issues. There are two outstanding issues in our current implementation. We believe all are manageable.

First, in practice, it is likely that SSPs will provide some protocol for deleting data early. We assume that any such out-of-band early-delete mechanism is carefully designed to maximize resistance to erroneous deletion by the data owner. For concreteness, we assume that the payment stream for SSP services is well protected by the data owner and that our SSP will delete data 90 days after payment is stopped. So, a data owner can delete unwanted data by creating a new account, copying a subset of data from the old account to the new account, and then stopping payment on the old account. More sophisticated variations (e.g., using threshold-key cryptography to allow a quorum of independent administrators to sign off on a delete request) are possible.

Second, SSFS is vulnerable to resource consumption attacks: although an attacker who controls an owner's local server cannot reduce the integrity of data stored at SSPs, the attacker can send large amounts of long-lived garbage data and/or extend expirations farther than desired for large amounts of the owner's data stored at the SSP. We conjecture that SSPs would typically employ a quota system to bound resource consumption to within some budget along with an out-of-band early delete mechanism such as described in the previous paragraph to recover from any resulting denial of service attack.

5.2 Local Server

Clients interact with SSFS through a local server. The SSFS local server is a user level file system that exports the NFS 2.0 interface to its clients. The local server serves requests from local storage to improve the cost, performance, and availability of the system. Remote storage is used to store data durably to guard against local failures. The local server encrypts (using SHA1 and 1024 bit Rabin key signature) and encodes [55] (if data is not fully replicated) all data before sending it to remote SSPs, and it transparently fetches, decodes and decrypts data from remote storage if it is not present in the local cache.

All local server state except the encryption key and list of SSPs is soft state: given these items, the local server can recover the full filesystem. We assume both are stored out of band (e.g., the owner burns them to a CD at installation time and stores the CD in a safety deposit box).

Snapshots: In addition to the standard NFS calls, the SSFS local server provides a snapshot interface [16]

that supports file versioning for achieving temporal isolation to tolerate client or administrator failures. A snapshot stores a copy in the local cache and also redundantly stores encrypted, erasure-coded data across multiple SSPs using the remote storage interface.

Local storage is structured carefully to reduce storage and performance overheads for maintaining multiple versions of files. SSFS uses block-level versioning [16, 53] to reduce storage overhead by storing only modified blocks in the older versions when a file is modified.

Other optimizations: SSFS uses a fast recovery optimization to recover quickly from remote storage when local data is lost due to local server failures (disk crashes, fire, etc.) The SSFS local server recovers quickly by coming online as soon as all metadata information (directories, inodes, and old-version information) is recovered and then fetching file data to fill the local cache in the background. If a missing block is requested before it is recovered, it is fetched immediately on demand from the SSPs. Additionally, local storage acts as a write-back cache where updates are propagated to remote SSPs asynchronously so that client performance is not affected by updates to remote storage.

6 Evaluation

To evaluate the practicality of the SafeStore architecture, we evaluate our SSFS prototype via microbenchmarks selected to stress test three aspects of the design. First, we examine performance overheads, then we look at storage space overheads, and finally we evaluate recovery performance.

In our base setup, client, local server, and remote SSP servers run on different machines that are connected by a 100 Mbit isolated network. For several experiments we modify the network to synthetically model WAN behavior. All of our machines use 933MHZ Intel Pentium III processors with 256 MB RAM and run Linux version 2.4.7. We use (3,2) erasure coding or full replication ((3,1) encoding) to redundantly store backup data across SSPs.

6.1 Performance

Figure 6 compares the performance of SSFS and a standard NFS server using the IOZONE [13] microbenchmark. In this experiment, we measure the overhead of SSFS's bookkeeping to maintain version information, but we do not take filesystem snapshots and hence no data is sent to the remote SSPs. Figure 6(a),(b), and (c) illustrates throughput for reads, throughput for synchronous and asynchronous writes, and throughput ver-

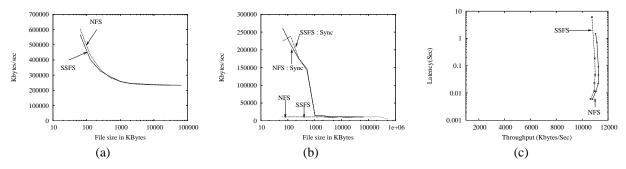

Fig. 6: IOZONE : (a) Read (b) Write (c) Latency versus Throughput

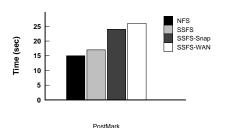

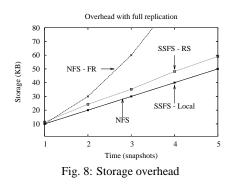

Fig. 7: Postmark: End-to-end performance

sus latency for SSFS and stand alone NFS. In all cases, SSFS's throughput is within 12% of NFS.

Figure 7 examines the cost of snapshots. Note SSFS sends snapshots to SSPs asynchronously, but we have not lowered the priority of these background transfers, so snapshot transfers can interfere with demand requests. To evaluate this effect, we add snapshots to the Postmark [19] benchmark, which models email/ecommerce workloads. The benchmark initially creates a pool of files and then performs a specified number of transactions consisting of creating, deleting, reading, or appending a file. We set file sizes to be between 100B and 100KB and run 50000 transactions. To maximize the stress on SSFS, we set the Postmark parameters to maximize the fraction of append and create operations. Then, we modify the benchmark to take frequent snapshots: we tell the server to create a new snapshot after every 500 transactions. As shown in the Figure 7, when no snapshots are taken SSFS takes 13% more time than NFS due to overhead involved in maintaining multiple versions. Turning on frequent snapshots increases the response time of SSFS (SSFS-snap in Figure 7) by 40% due to additional overhead due to signing and transmitting updates to SSPs. Finally, we vary network latencies to SSPs to study the impact of WAN latencies on performance when SSPs are geographically distributed over the Internet by introducing artificial delay (of 40 ms) at the SSP server. As shown in the Figure 7, SSFS-WAN

response time increases by less than an additional 5%.

6.2 Storage overhead

Here, we evaluate the effectiveness of SSFS's mechanisms for limiting replication overhead. SSFS minimizes storage overheads by using a versioning system that stores the difference between versions of a file rather than complete copies [53]. We compare the storage overhead of SSFS's versioning file system and compare it with NFS storage that just keeps a copy of the latest version and also a naive versioning NFS file system (NFS-FR) that makes a complete copy of the file before generating a new version. Figure 8 plots the storage consumed by local storage (SSFS-LS) and storage at one remote server (SSFS-RS) when we use a (3,1) encoding. To expose the overheads of the versioning system, the microbenchmark is simple: we append 10KB to a file after every file system snapshot. SSFS's local storage takes a negligible amount of additional space compared to non-versioned NFS storage. Remote storage pays a somewhat higher overhead due to duplicate data storage when appends do not fall on block boundaries and due to additional metadata (integrity hashes, the signed write request, expiry time of the file, etc.)

The above experiments examine the case when the old and new versions of data have much in common and test whether SSFS can exploit such situations with low overhead. There is, of course, no free lunch: if there is little in common between a user's current data and old data, the system must store both. Like SafeStore, Glacier uses a expire-then-garbage collect approach to avoid inadvertent file deletion, and their experience over several months of operation is that the space overheads are reasonable [40].

7 Related work

Several recent studies [31, 57] have identified the challenges involved in building durable storage system for multi-year timescales.

Flat erasure coding across nodes [33, 36, 40, 66] does not require detailed predictions of which sets of nodes are likely to suffer correlated failures because it tolerates any combinations of failures up to a maximum number of nodes. However, flat encoding does not exploit the opportunity to reduce replication costs when the system can be structured to make some failure combinations more likely than others. An alternative approach is to use *full replication* across sites that are not expected to fail together [43, 46], but this can be expensive.

SafeStore is architected to increase the likelihood that failures will be restricted to specific groups of nodes, and it efficiently deploys storage within and across SSPs to address such failures. Myriad [34] also argues for a 2-level (cross-site, within-site) coding strategy, but SafeStore's architecture departs from Myriad in keeping SSPs at arms-length from data owners by carefully restricting the SSP interface and by including provisions for efficient end-to-end auditing of black-box SSPs.

SafeStore is most similar in spirit to OceanStore [42] in that we erasure code indelible, versioned data across independent SSPs. But in pursuit of a more aggressive "nomadic data" vision, OceanStore augments this approach with a sophisticated overlay-based infrastructure for replication of location-independent objects that may be accessed concurrently from various locations in the network [54]. We gain considerable simplicity by using a local soft-state server through which all user requests pass and by focusing on storing data on a relatively small set of specific, relatively conventional SSPs. We also gain assurance in the workings of our SSPs through our audit protocol.

Versioning file systems [16, 50, 56, 59, 64] provide temporal isolation to tolerate client failures by keeping multiple versions of files. We make use of this technique but couple it with efficient, isolated, audited storage to address a broader threat model.

We argue that highly durable storage systems should audit data periodically to ensure data integrity and to limit worst-case MTTR. Zero-knowledge-based audit mechanisms [38, 47] are either network intensive or CPU intensive as their main purpose is to audit data without leaking any information about the data. Safe-Store avoids the need for such expensive approaches by encrypting data before storing it. We are then able to offload audit duties to SSPs and probabilistically spot check their results. LOCKSS [46] and Samsara [37] audit data in P2P storage systems but assume that peers store full replicas so that they can easily verify if peers store identical data. SafeStore supports erasure coding to reduce costs, so our audit mechanism does not require SSPs to have fully replicated copies of data.

8 Conclusion

Achieving robust data storage on the scale of decades forces us to reexamine storage architectures: a broad range of threats that could be neglected over shorter timescales must now be considered. SafeStore aggressively applies the principle of *fault isolation* along administrative, physical, and temporal dimensions. Analysis indicates that SafeStore can provide highly robust storage and evaluation of an NFS prototype suggests that the approach is practical.
