Author Retrospective for

Optimizing for Parallelism and Data Locality

Kathryn S. McKinley

mckinley@microsoft.com

ABSTRACT

Today there is an urgent need for algorithms, programming language systems and tools, and hardware that deliver on the potential of parallelism due to the end of Dennard scaling. This work (from my PhD dissertation, supervised by Ken Kennedy) was one of the early papers to optimize for and experimentally explore the tension between data locality and parallelism on shared memory machines. A key result was that false sharing of cache lines between processors with local caches on separate chips was disastrous to the performance and scaling of applications. This retrospective includes a short personal tour through the history of parallel computing, a discussion of locality and parallelism modeling versus a polyhedral formulation of optimizing dense matrix codes, and how this problem is still relevant to compilers today. I end with a short memorial to my deceased co-author and advisor Ken Kennedy.

Parallel Computing: A Personal History

Parallel computing seemed to be entering its heyday in the late 1980s and early 1990s. At Rice in 1989, Ken Kennedy was awarded an NSF Science and Technology Center for the Center for Research on Parallel Computing (CRPC) as the Principal Investigator. The CRPC started with seven sites and eventually included 400 researchers, staff, and graduate students. Their technical expertise spanned parallel algorithms, compilers, runtimes, and hardware. The CRPC vision that Ken, his collaborators, and students shared was to invent parallel algorithms for critical problems in science, coupled with programming language tools, such as compilers, runtime systems, and programming environments, that made them run fast. We were not trying to solve the dusty-deck problem of automatically converting sequential algorithms to parallel ones. We understood that parallel and sequential algorithms for the same problem require different solutions. However, tools would do heavy lifting to map application parallelism to hardware parallelism, such that the programmers would not have to reimplement their algorithms for each new parallel architecture. A key aspect of this problem is balancing parallelism, sharing between tasks, and memory usage, which was the topic our paper addressed.

In this same period, a number of established companies and startups, such as Sequent, had introduced parallel machines. The Sequent Symmetry was the machine on which we reported our results. It was not yet clear that the research and development challenges of parallel computing would make it too costly to win in the market place in the short term. By the mid 1990s, this generation of parallel computers together with some of the companies that built them were pulled under by the economic tide and huge success of personal computers with a single processor. Clock scaling was delivering exponential performance improvements. Sequential software was easier to build; the sequential programming interface was stable across generations of hardware and software; and hardware was twice as fast every 18 months. Why invest in parallel computing?

In hindsight, abandoning sustained national funding, much research, and advanced development on parallel computing was a mistake. Today, leakage power and other manufacturing challenges at small feature sizes have ended Dennard scaling and will soon end Moore’s Law. Vendors have turned to parallelism as a strategy to continue increasing computer capacity to meet computational demands in science, government, and consumer markets. However, researchers and companies are still struggling to deliver on the potential of parallelism. For example, even though manufacturers can fit 20 to 100 processors on a single chip, many commodity server, client, and mobile chips have 1 to 12 CPUs with 2 to 24 hardware contexts. Building, compiling for, programming, and porting software between parallel systems is still hard.

Parallelism and Data Locality

Part of the reason programming and optimizing parallel machines, even shared memory machines, is hard is due to real sharing and false sharing of data between parallel tasks. In a typical shared memory parallel machine, each CPU has some amount of private cache memory and some shared main memory. In the 1990s, the CPUs were on separate chips and today they are on the same chip, but the basic memory hierarchy structure is similar.

Hardware caches exploit the observation that programs often exhibit temporal locality — they reuse the same data — and spatial locality — they access adjacent data elements — close together in time. For example, a loop that sequentially iterates over a vector of
integers (allocated as a single vector) exhibits spatial locality with a reuse distance of one iteration. Caches store the most recently used items and cache lines typically contain between 32 B to 256 B of data. The fewer accesses between reuse of data on the same cache line, the more likely the cache will be to still hold the line. Unfortunately, since the architecture only moves and tracks data at a cache line granularity, false sharing occurs when two tasks on different CPUs want to write independent data that resides on the same cache line at the same time, they cannot. Only one cache can write the line at a time, which requires invalidating and moving the cache line, serializing execution.

Figure 1 in the paper shows the effect of false sharing on 18 processors of a Sequent shared-memory parallel machine executing an addition of three 2D dense matrices and storing the result. For the same amount of work, without false sharing, a speedup of 18 (best) is possible. With false sharing, speedup ranges between 6 and 9 (mem). That figure would have been better labeled “False sharing more than halves speedup.”

The remainder of the paper presents an optimization algorithm for dense matrices that seeks (1) to minimize the reuse distance for cache lines for each parallel task, (2) to introduce parallelism at the outermost loop possible, and (3) to eliminate false sharing by strip mining, such that the outer loop is parallel and each parallel iteration never shares a cache line with another parallel iteration.

The algorithm uses data dependence analysis to detect parallelism and temporal reuse [4, 5, 12]. It precisely computes spatial and temporal cache line reuse on inner loops and then generalizes to the entire loop nest. It next determines the loop ordering that maximizes expected cache line reuse, and directly permutes the loops to this order or the closest legal loop order. The next phase introduces parallelism at the coarsest possible granularity (outermost loop) without causing false sharing. It uses a combination of loop permutation and strip mining. A machine specific cost model determines if the parallel loop is of sufficient granularity to deliver speedups. If the parallel loop also provides cache line reuse, the algorithm strip mines the loop based on the line size and number of processors, permuting the iterator loop to the outermost legal position and leaving the strips of consecutive iterations with reuse in place to deliver cache locality. This transformation process ensures that none of the outermost parallel loop iterations share cache lines, eliminating false sharing.

**Historical Positioning**

Our work on optimizing compilers for parallel architectures at Rice was greatly influenced by the research at UIUC, IBM, and Stanford. David Kuck and his PhD students at UIUC introduced the first analyses and optimizations in this area. For example, Uptal Banerjee introduced the first practical dependence tests to detect parallelism [4, 5] and Abu-Sufah introduced the first optimizations for improving data locality [1]. Allen and Kennedy showed how to use dependences to correctly permute loops and introduce parallelism [3], and with Callahan, subsequently showed how to maximize the granularity of parallelism [2].

Irigoin and Trioloit introduced the use of a polyhedral model of dependences to increase parallelism [14] and the work of Wolf and Lam extended this theory to introduce parallelism at all possible levels [28]. Wolf and Lam also used this theory to produce all the legal loop permutations and loop skews and then selected the one that maximized cache reuse [27], however they did not consider both locality and parallelism at once.

At the time, the polyhedral and unimodular models were restricted to permuting, reversing, and skewing perfectly nested loops operating on dense matrices. Optimizing one loop in isolation was and is not sufficient for the best performance; data reorganization, loop fusion, and loop distribution add substantial benefits [7, 10, 11, 16, 21, 22, 25]. Our model directly computed the best permutations for locality and parallelism and we showed [7, 16, 20] how to directly derive good loop fusion and distribution choices, which the polyhedral model could not yet perform. Our approach also had the advantage that the resulting code was human readable and suitable for use in an interactive parallelization tool [17]. Several commercial tools implemented our approach, including the DEC Alpha compiler.

Today, the polyhedral approach combines fusion and distribution with other loop optimizations [11, 22, 25] and is in wide use in commercial and research compilers. These techniques use heuristic search based on models, some similar to our model, to specialize code for a variety of parallel architectures.

Loop nest optimization remains an active area of research [11, 22, 25], in part, because each generation of parallel hardware offers new challenges and opportunities. Using the compiler to adapt applications to a parallel machine achieves portability and high performance, substantially reducing developer effort. Loop optimizations are critical to optimization in many modern settings, including GPPUs [18], high-level hardware synthesis [8, 19, 24], auto-tuning [9, 23, 25], and library construction [13, 26].

None of the early work on locality or parallelism considered false sharing and locality and parallelism interactions. Our paper highlighted the problems that false sharing caused, which subsequently other researchers also sought to eliminate. For example, Jeremiah and Eggars transformed data with padding [15] and Ding and Kennedy performed array regrouping [10] to eliminate false sharing and improve locality. Later my PhD student Emery Berger, others, and I showed how the Hoard memory allocator avoided false sharing to produce more scalable performance, compared to prior C/C++ memory allocators [6]. The Hoard algorithm is now widely used, for example, in Apple’s iOS.

**Professor Ken Kennedy (1945 - 2007)**

Ken loved his research and bringing people together on both a small and large scale. He founded the Rice Computer Science Department in 1985, CRPC, the Los Alamos Computer Science Institute (LACSI), and co-chaired with Bill Joy, the President’s Information Technology Advisory Committee (PITAC) from 1997 to 1999. This first PITAC committee initiated the NSF ITR program, which funded the research of 1000s of faculty and graduate students over a 10 year period. In his own research life, he could not bear to cut back on people or research; he would instead raise more money. He felt it was a personal failure if any student who worked with him did not graduate and graduated over 40 PhD students. Together with his students and colleagues, he invented programming language technologies still in use today, such as register allocation, strength reduction, prefetching, loop transformations for scalar, vector, and parallel architectures (this paper is an example), interprocedural analyses, interactive parallel programming tools, FortranD, and telescoping languages.

In the last few years of his life as he struggled with pancreatic cancer, he kept working because he loved his life, his students, and his work. Ken laughed a lot and really loudly, especially at his own jokes. I still miss him.

**Acknowledgements** I would like to thank again my graduate student colleagues Chau-Wen Tseng, Preston Briggs, Cliff Click, Er- van Darnell, and Nathaniel McIntosh for their contributions to this work. I would also like to thank them as well as David Callahan, Keith Cooper, Mark Hall, Mary Hall, Seema Hiranandani, Marina
Kalem, Amy Pullen, Linda Torezcon, and Scotty Strahan (my husband) for making graduate school a wonderful personal and intellectual experience. I thank the anonymous reviewer for improving the first version and Steve Blackburn, Mary Hall, and Todd Mytkowicz for discussions and comments on this version.

Abstract
Previous research has used program transformation to introduce parallelism and to exploit data locality. Unfortunately, these two objectives have usually been considered independently. This work explores the trade-offs between effectively utilizing parallelism and memory hierarchy on shared-memory multiprocessors. We present a simple, but surprisingly accurate, memory model to determine cache line reuse from both multiple accesses to the same memory location and from consecutive memory access. The model is used in memory optimizing and loop parallelization algorithms that effectively exploit data locality and parallelism in concert. We demonstrate the efficacy of this approach with very encouraging experimental results.

1 Introduction
Transformations to exploit parallelism and to improve data locality are two of the most valuable compiler techniques in use today. Independently, each of these optimizations has been shown to result in dramatic improvements. This paper seeks to combine the benefits of both by using a simple memory model to drive optimizations for data locality and parallelism. By unifying the treatment of these optimizations, we are able to place loops with data reuse on inner loops and to introduce parallelism for outer loops. Our strategy produces data locality at the innermost loops, where it is most likely to be exploited by the hardware and places parallelism at the outermost loop, where it is most effective. If these two goals conflict, we present an algorithm that usually reaps the benefits of both.

Optimizing data locality is necessarily both architecture and language dependent. However, the reuse of memory locations and the consecutive access of adjacent memory locations form the foundation of most memory hierarchy optimizations. Reuse of a particular memory reference for arrays can be discovered using data-dependence analysis [KKP83]. However, reuse of consecutive accesses, often called unit stride access, is a significant source of reuse that can easily be determined when the storage order of arrays and the cache line size is known. In this paper we introduce a simple model for estimating the cost, in memory references, of executing a given loop nest. The principal advantage of this model over previous models is that it takes into account cache reuse due to consecutive accesses to the same cache line. We show how this model can be used to exploit data locality at multiple levels via loop permutation.

Parallelism is usually most effective when it achieves the highest possible granularity, the amount of work per parallel task. Granularity is highest when parallel tasks contain the largest amount of work possible. In this paper, parallelism is introduced via the parallel loop construct for shared-memory multiprocessors. Our algorithm first uses the memory model to find a loop organization that exploits data locality. It then seeks to parallelize the outermost loop or a parallel loop that can be positioned outermost. Given sufficient iterations, it then strip mines the loop into two loops, such that one loop is used to achieve locality and the other is used to introduce parallelism.

1.1 Matrix Multiply Example
As an example of this process, consider the ubiquitous matrix multiply.

\[
\begin{align*}
\text{DO } J & = 1, N \\
\text{DO } K & = 1, N \\
\text{DO } I & = 1, N \\
C(I,J) & = C(I,J) + A(I,K) * B(K,J)
\end{align*}
\]

Assuming arrays are stored such that columns of the arrays are in consecutive memory locations, i.e., column-major order, this loop organization exploits data locality in the following manner. The consecutive access on the inner I loop to C(I,J) and A(I,K) provides an opportunity for cache line reuse when the cache line size is greater than 1. There is also a loop-invariant reuse of B(K,J) on the I loop. Additionally, the J and the K loops can be parallel. However, if the number of processors, P, is less than the number of iterations of either loop, it is not profitable to utilize both levels of parallelism at once due to additional scheduling overhead. A better execution time would result by maximizing the granularity of one level of the parallelism and then matching

it to the machine. If \( N = P \), selecting \( J \) to be executed in parallel preserves data locality and introduces a single level of parallelism with maximum granularity.

\[ \text{PARALLEL DO } J = 1, N \]
\[ \text{DO } K = 1, N \]
\[ \text{DO } I = 1, N \]
\[ C(LJ) = C(LJ) + A(LK) * B(KJ) \]
However, if the number of loop iterations is greater than the number of processors, \( N > P \), it is often useful to combine independent iterations into a single parallel task to achieve granularity that matches the machine.

The parallel loop is strip mined by the number of processors where the strip size is \( SS = \lceil N / P \rceil \). We call the \( J \) loop the strip and the \( JJ \) loop, which walls between strips, the iterator.

\[ \text{PARALLEL DO } JJ = 1, N, SS \]
\[ \text{DO } J = JJ, \text{MIN}(JJ + SS - 1, N) \]
\[ \text{DO } K = 1, N \]
\[ \text{DO } I = 1, N \]
\[ C(LJ) = C(LJ) + A(LK) * B(KJ) \]

The parallel \( JJ \) loop carves up the data space nicely, but if each processor's cache is still not large enough to contain all of array \( A \), tiling the loop nest further improves performance by providing reuse of \( A \). Tiling combines strip mining and loop interchange to promote reuse across a loop nest \([\text{IT88}, \text{Wol89a}]\). For matrix multiply, the loop nest may be tiled by strip mining the \( K \) loop by \( TS \) and then interchanging it with \( J \).

\[ \text{PARALLEL DO } JJ = 1, N, SS \]
\[ \text{DO } KK = 1, N, TS \]
\[ \text{DO } J = JJ, \text{MIN}(JJ + SS - 1, N) \]
\[ \text{DO } K = KK, \text{MIN}(KK + B - 1, N) \]
\[ \text{DO } I = 1, N \]
\[ C(LJ) = C(LJ) + A(LK) * B(KJ) \]

Here, \( TS \) is selected based on the cache size. This organization moves the reuse of \( A(2:NN,KK+TS-1) \) on the \( J \) loop closer together in time, making it more likely to still be in cache.

This optimization approach may be divided into three phases:
1. optimizing to improve data locality,
2. finding and positioning a parallel loop, and
3. performing low-level memory optimizations such as tiling for cache and placing references in registers \([\text{LRW91}, \text{CCK90}]\).

This paper focuses on the first two phases. We advocate the first two phases be followed by a low-level memory optimizing phase, but do not address it here.

The remainder of this paper is divided into 10 sections. We first present some terms used in this paper to describe data dependence and the machine model. The next section explores and illustrates the effects of parallelism and memory access on performance. The next two sections present a cost model for determining reuse and an algorithm for improving it. Section 6 describes the parallelization strategy. The overall strategy combines the two in Section 7. In Section 8, experimental results are reported. We then overview related work and conclude.

2 Background

2.1 Data Dependence

Dependence analysis is the compile-time analysis of a program's memory accesses. A data dependence between two references \( Rf_1 \) and \( Rf_2 \) indicates that they read or write a common memory location \([\text{KKP+81}]\). True, anti, and output dependences arise when at least one reference is write; the order between \( Rf_1 \) and \( Rf_2 \) must be preserved to maintain the semantics of the original program. Input dependences arise if both \( Rf_1 \) and \( Rf_2 \) are reads; they do not restrict program order.

Data dependences may be characterized by their access patterns between loop iterations. The number of loop iterations \( d \) separating the source and sink of the dependence is its dependence distance \([\text{KMC72}, \text{Lam74}]\); it may also be summarized as a dependence direction consisting of \(<, =, \text{ or } >\) \([\text{WIB87}, \text{Wol88b}]\).

Dependence distances and directions are represented as a vector whose elements, displayed left to right, represent the dependence from the outermost to the innermost loop in the nest. By definition all distance and direction vectors are lexicographically positive. We use \( \delta = (\delta_1, \ldots, \delta_n) \) to represent a distance or direction vector, where \( \delta_i \) is the dependence distance or direction for the loop at level \( i \).

Dependences may also be characterized as either loop-independent or loop-carried. Loop-independent dependences occur on the same iteration of a loop. A dependence between iterations of a loop is called loop-carried and prevents the iterations of a loop from being executed in parallel \([\text{AK87}]\). A dependence is carried by the outermost loop for which the element in the direction vector is not an `='.

Data dependence is used to determine the legality of a given loop permutation by checking whether any permuted true, anti, or output dependence vector becomes lexicographically negative \([\text{Ban90b}, \text{WI90}]\). Data dependence also characterizes reuse of individual memory locations \([\text{CCK90}]\).

2.2 Memory and Language Model

The techniques developed in this paper are intended for shared-memory multiprocessors where each processor has at a local cache and the processors are connected with a common bus. Because we are evaluating reuse, we require some knowledge of the memory hierarchy. However, because our model is very simple, only minimal knowledge of the cache is required; the compiler must know the cache line size (CLS). The size, set associativity, and replacement policy of the cache are not important here. In addition, we assume a write-back cache and ignore non-unique write references. If the cache is write-through, these writes should be included.

In addition, we only concern ourselves with memory
speed-up
mem (I out,M=2:18,N=18)
gran (J out,N=2:18,M=18)
worst (I out,M=2:18,N=18)

Figure 1: Memory and parallelism tradeoffs

accesses caused by array references, since they dominate memory access in scientific Fortran codes. We also assume that arrays are stored in column-major order, where unit stride accesses in the first array dimension translate into contiguous memory accesses. Our results are also valid for row-major arrays such as those found in C with only minor changes.

3 Tradeoffs in Optimization

This section illustrates with an experiment the influence of memory reuse and parallelism granularity on speed-up. As expected, it indicates the best performance is possible only when both are utilized effectively in concert. It also shows that when both cannot be achieved at once, there are situations where favoring one or the other results in the best execution time. Neither always dominates. To illustrate, we phrase the following question.

Given enough computation to make parallelism profitable, what is the effect of reuse and how should it affect the optimization strategy?

Figure 1 presents the results of executing different parallel versions of the following loop nest on 18 processors of a Sequent Symmetry S81 with 20 processors, with increasing amounts of total work.

\[
\begin{align*}
\text{DO } & \text{ J = 1, N} \\
\text{DO } & \text{ I = 1, M} \\
\text{DO } & \text{ H = 1, L} \\
C(I, J) &= C(I, J) + A(I, J) + B(I, J)
\end{align*}
\]

The total amount of work is increased by varying the upper bounds \(N\) and \(M\) from 2 to the number of processors \((P = 18)\). We consider positioning \(I\) or \(J\) as the outer parallel loop in the nest. In Figure 1, the best version of this loop nest has an outer parallel \(J\) loop with 18 iterations \((N = 18)\) and total work is increased by varying \(M\) from 2 to 18. Each of the 18 processors accesses distinct columns of each array. This organization exploits cache line reuse on each processor and results in linearly-scalable speed-up.

When the \(J\) loop is outermost and the number of parallel iterations of \(I\) is varied from 2 to 18 along with \(P\) and the \(I\) loop contains 18 iterations, the total amount of work increases, but the work per processor remains the same. This organization is illustrated by the gran line. In this case, the speed-ups scales by the number of parallel iterations, but cache line reuse is still facilitated on each processor.

If instead the \(I\) loop is made outermost and parallel, then processors must compete for the cache line which contains \(C(I,J)\) in order to write it. This competition is called false sharing. In addition, multiple processors require cache lines containing \(A(I,J)\) and \(B(I,J)\), increasing network contention and total memory utilization. When the number of parallel iterations of the \(I\) loop as outermost varies from 2 to 18 along with \(P\) and the \(J\) loop contains 18 iterations, the worst line indicates the performance. If the number of parallel iterations of \(I\) is held at 18 while the \(J\) loop is varied from 2 to 18, the mem line results.

Compare the pair of lines best and mem. The factor of two difference is due to the benefit of cache line reuse in best, and the limitations of false sharing and increased bus and memory utilization in mem. The same comparison holds for the gran and worst lines. These results indicate that the parallelizing algorithm must recognize reuse and false sharing to be effective.

Now compare the pair of crossing lines gran and mem. These computations differ only by an interchange. An optimization strategy that only used loop interchange would be forced to pick between the two. To obtain the best performance for this example, the \(J\) loop would be outermost when \(N > 8\), otherwise the \(I\) loop should be outermost. In addition, this 'crossover' point would need to be determined for each computation, a daunting task. Our approach instead combines loop interchange and strip mining in a parallelization strategy that minimizes false sharing and exploits data reuse.

4 Optimizing Data Locality

In this section we describe two sources of data reuse, then we incorporate both in a simple yet realistic cost model. In subsequent sections, this cost model is used to guide optimizations for improving data locality and exploiting parallelism.

4.1 Sources of Data Reuse

We first consider the two major sources of data reuse.
• multiple accesses to the same memory location
• accesses to consecutive memory locations (i.e., stride 1 or unit stride access)

Multiple accesses to the same memory location may arise from either a single array reference or multiple array references. These accesses are loop-independent if they occur in the same loop iteration, and are loop-carried if they occur on different loop iterations. This type of reuse is called temporary reuse. The most obvious source of temporal reuse is from loop-invariant references. For instance, consider the reference to \( A(J) \) in the following loop nest. It is invariant with respect to the \( I \) loop, and is reused by each iteration.

\[
\text{DO } J = 1:N \\
\text{DO } I = 1:N \\
\text{S = S + A(J) + B(I) + C(J,J)}
\]

A second source of data reuse is caused by multiple accesses to consecutive memory locations. For instance, each cache line is reused multiple times on the inner \( I \) loop for \( B(I) \) in the above example. This reuse is called spatial reuse. The actual amount of reuse is dependent on the size of \( B(I) \) relative to the cache line size and the pattern of intervening references. For the rest of this paper, we assume for simplicity that the cache line size is expressed as a multiple of the number of array elements. For reasonably large computations, references such as \( C(J,J) \) do not provide any reuse on the \( I \) loop, because the desired cache lines have been flushed by intervening memory accesses.

Previous researchers have studied techniques for improving locality of accesses for registers, cache, and pages [AS79, CCK90, WL91, GJG88]. In this paper we concentrate on improving the locality of accesses for cache; i.e., we attempt to increase the locality of access to the same cache line. Empirical results show that improving spatial reuse can be significantly more effective than techniques that consider temporal reuse alone [KMT92]. In addition, consecutive memory access results in reuse at all levels of the memory hierarchy except for registers.

4.2 Simplifying Assumptions

To simplify analysis we make two assumptions. First, our loop cost function assumes that reuse occurs only across iterations of the innermost loop. This assumption decreases precision but greatly simplifies analysis, since it allows the number of cache line accesses to be calculated independent of the permutation of all outer loops. This assumption is accurate if the inner loop contains a sufficiently large number of memory accesses to completely flush the cache after executing all of its iterations. We show later that our optimizations to improve locality can select a desirable permutation of outer loops even with this restriction.

4.3 Loop Cost Function

Given these assumptions, we present a loop cost function \textit{LoopCost} based on our memory model. Its goal is to estimate the total number of cache lines accessed when a candidate loop \( l \) is positioned as the innermost loop. The result is used to guide loop permutation to improve data locality. The estimate is computed in two steps. First, references that will access the same cache line in the same or different iterations of the \( l \) loop are combined using \textit{RefGroup}. Second, the number of cache lines accessed by all groups is calculated using \textit{LoopCost}.

4.4 RefGroup

The goal of the \textit{RefGroup} algorithm is to partition variable references in the program text into \textit{reference groups} such that all references in a group access the same memory location, and consequently the same
cache line. Wolf and Lam call these groups \textit{equivalence classes} exhibiting \textit{group-temporal} reuse. The partition process is particularly simple here because we only consider reuse for each loop when it is positioned innermost.

Two references are in the same reference group for loop \( l \) if they actually access some common memory location (data dependence \( \delta \) exists between them), and the reuse occurs on \( l \) if it is positioned as the innermost loop. The common accesses then occur on either the same iteration of \( l \) (\( \delta_l = 0 \)) or across \( d \) iterations of \( l \) (\( \delta_l = d \)). More formally we define \textit{RefGroup} as follows.

\textbf{Definition:} Two references \( \text{Ref}_1 \) and \( \text{Ref}_2 \) belong to the same \textit{reference group} with respect to loop \( l \) if and only if:

1. \( \exists \delta \text{Ref}_1 \delta \text{Ref}_2 \), and

2. \( \delta \) is a loop-independent dependence, or \( \delta_l \), the entry in \( \delta \) corresponding to loop \( l \), is a constant \( d \) (\( d \) may be zero) and all other entries are zero.

\subsection*{4.4.1 Jacobi Example}

For instance, consider the following Jacobi iteration example.

\begin{verbatim}
DO I = 2N+1
   DO J = 2N+1
      A(J,J) = 0.2*(B(JJ) + B(J-1,J) + B(J+1,J)
               + B(J,J-1) + B(J,J+1))
   \end{verbatim}

Data dependences connect all references to \( B \). The reference groups for the \( I \) loop are:

\{A(J,J), B(J,J), B(J,J-1), B(J,J+1)\},
\{B(J,J), B(J,J+1)\}.

The reference groups for the \( J \) loop are:

\{A(J,J), B(J,J), B(J,J-1), B(J,J+1)\},
\{B(J,J), B(J,J+1)\}.

Algorithm \textit{RefGroup} is shown in Figure 2. Its efficiency may be improved by pruning all identical array references, since they access the same memory location on each iteration and always fall in the same reference group.

\subsection*{4.5 LoopCost}

After the number of reference groups for loop \( l \) is computed with \textit{RefGroup}, the algorithm \textit{LoopCost} is applied to estimate the total number of cache lines that would be accessed by each reference group if \( l \) were the innermost loop. Once again, the task is simplified because we only consider reuse between iterations of \( l \).

\textit{RefCost} works by considering one array reference \( \text{Ref} \) from each reference group; these representative references are classified as loop-invariant, consecutive, or non-consecutive with respect to loop \( l \). Loop-invariant array references have subscripts that do not vary with \( l \); they require only one cache line for all iterations of \( l \).\footnote{Of course, loop-invariant references should eventually be put in registers by later optimizations [CC90].} Consecutive array accesses vary with \( l \) only in the first subscript dimension. They access a new cache line every \( ds \) iterations, resulting in \( trip/ds \) cache line accesses, assuming \( l \) performs \( trip \) iterations. Fewer cache lines are reused for nonunit strides. Non-consecutive array accesses vary with \( l \) in some other subscript dimension; they access a different cache line each iteration, yielding a total of \( trip \) cache line accesses.

Once \textit{RefCost} is computed, the algorithm \textit{LoopCost} calculates the total number of cache lines accessed by all references when \( l \) is the innermost loop. It simply sums \textit{RefCost} for all reference groups, then multiplies the result by the trip counts of all the remaining loops. This calculation will underestimate the number of cache lines accessed on the inner loop, if the distance of the dependences for a particular \textit{RefGroup} set are greater than \( ds \). Also, slight underestimates occur because the exact alignment of arrays in memory is not known until run-time. \textit{LoopCost} will overestimate the number of cache lines, if there is additional reuse across an outer loop.

\textit{LoopCost} is expressed more formally in Figure 3 for the following loop nest containing one array reference from each reference group \( \text{RefGroup}_1 \ldots \text{RefGroup}_m \):

\begin{verbatim}
   \begin{align*}
      \text{do } & i_1 = lb_1, ub_1, s_1 \\
      \text{do } & i_2 = lb_2, ub_2, s_2 \\
      \quad \text{\ldots} \\
      \text{do } & i_m = lb_m, ub_m, s_m \\
      \text{\quad \text{Ref}_{f_1}(i_1, \ldots, i_n) \\
      \quad \text{\ldots} \\
      \text{\quad \text{Ref}_{m}(g_1(i_1, \ldots, i_n))} \\
   \end{align*}
\end{verbatim}

Note that \textit{LoopCost} can be used to calculate cache line accesses even for array references with complex subscript expressions. For instance, it determines that \( A(I+J+N) \) results in consecutive memory accesses with respect to both the \( I \) and \( J \) loops.

\subsection*{4.6 Imperfectly Nested Loops}

Because of their simplicity, both \textit{RefGroup} and \textit{LoopCost} can also be applied to imperfectly nested loops. Consider the following example, where the first definition of \( A(J) \) is imperfectly nested:

\begin{verbatim}
   \begin{align*}
      \text{DO } & J = 1, 100 \\
      \text{A(J)} = 0 \\
      \text{DO } & I = 1, 100 \\
      \text{A(J) = A(J) + \ldots} \\
   \end{align*}
\end{verbatim}

\textit{RefGroup} would place all references to \( A(J) \) in the same reference group. When we apply \textit{RefCost} to calculate the number of cache lines accessed by a reference group, we need to select the most deeply nested member of
Figure 3: Algorithm LoopCost

INPUT:
\[ \mathcal{L} = \{ l_1, \ldots, l_n \} \] a loop nest with headers \( \mathbf{l}_{\text{b}}, \mathbf{u}_{\text{b}}, s \)
\[ \mathcal{R} = \{ \text{Ref}_1, \ldots, \text{Ref}_m \} \] representatives from each reference group
\( \text{trip}_k = (u_{\text{b}} - l_{\text{b}} + s_{\text{b}})/s_{\text{b}} \)   
\( c_{\text{ds}} \) the cache line size,
\( \text{appear}(f) \) = the set of index variables that appears in the subscript expression \( f \)
\( \text{coeff}(i_k, f) \) = the coefficient of the index variable \( i_k \) in the subscript \( f \) (it may be zero)

OUTPUT:
\[ \text{LoopCost}(l) = \text{number of cache lines accessed with } l \text{ as innermost loop} \]

ALGORITHM:
\begin{align*}
\text{LoopCost}(l) = \sum_{k=1}^{m} \left( \text{RefCost}(\text{Ref}_k, f_1, \ldots, f_n) \right) \times \prod_{h \neq l} \text{trip}_h \\
\text{RefCost}(\text{Ref}_k) = \\
1 \quad \text{if } (i_k \notin \text{appear}(f_1)) \land \ldots \land (i_k \notin \text{appear}(f_j)) \text{ loop invariant} \\
\text{trip}/c_{\text{ds}} \quad \text{if } (i_k \in \text{appear}(f_1)) \land (\text{coeff}(i_k, f_1) = 1) \land (|s_{\text{b}}| = 1) \land \\
(i_k \notin \text{appear}(f_j)) \text{ unit stride} \\
\text{trip} \quad \text{otherwise} \text{ no reuse}
\end{align*}

the group. LoopCost then multiplies the result by the trip counts of all the loops that actually enclose the reference.

5 Loop Permutation

The previous section presents our cost model for evaluating the data locality of a given loop structure with respect to cache. In this section we show how the simplicity and accuracy of the cost model guides loop permutation to restructure a loop nest for better data locality.

A naive optimization algorithm would simply generate all legal loop permutations and select the permutation that yields the best estimated data locality using LoopCost. Unfortunately, generating all possible loop permutations takes time that is exponential in the number of loops and can be very expensive in practice. It becomes increasingly unappealing when transformations such as strip mining introduce even larger search spaces.

Instead of testing all possible permutations, we show how our cost model allows us to design an algorithm to directly compute a preferred loop permutation.

5.1 Memory Order

The locality evaluating function LoopCost does not calculate data reuse on outer loops; however, we can still restructure programs to exploit outer loop reuse. The key insight is that if loop \( l \) causes more reuse than loop \( l' \) when both are considered as innermost loops, \( l \) will also promote more reuse than \( l' \) when both loops are placed at the same outer loop position.

LoopCost can thus be considered to be a measure of the reuse carried by a loop. This allows us to select a desired permutation of loops called memory order that yields the best estimated data locality. We simply rank each loop \( l \) using LoopCost, ordering the loops from outermost to innermost \( (l_1 \ldots l_n) \) such that LoopCost\((l_{-1}) \geq \text{LoopCost}(l_i)\).

5.1.1 Memory Order Algorithm

The algorithm MemoryOrder is defined as follows. It computes LoopCost for each loop, sorts the loops in order of decreasing cache line accesses (i.e. increasing reuse), and returns this loop permutation.

5.1.2 Example

As an example, recall matrix multiply. We compute memory order with \( c_{\text{ds}} = 4 \). The reference groups for matrix multiply put the two references to \( C_{(I,J)} \) in the same group on all the loops and \( A_{(I,K)} \) and \( B_{(K,J)} \) are placed in separate groups. LoopCost computes the relative reuse on each of the loops as seen below.

<table>
<thead>
<tr>
<th>references</th>
<th>( J )</th>
<th>( K )</th>
<th>( I )</th>
</tr>
</thead>
<tbody>
<tr>
<td>( C_{(I,J)} )</td>
<td>( n \cdot n^2 )</td>
<td>( 1 \cdot n^2 )</td>
<td>( 1/4n \cdot n^2 )</td>
</tr>
<tr>
<td>( A_{(I,K)} )</td>
<td>( 1 \cdot n^2 )</td>
<td>( n \cdot n^2 )</td>
<td>( 1/4n \cdot n^2 )</td>
</tr>
<tr>
<td>( B_{(K,J)} )</td>
<td>( n \cdot n^2 )</td>
<td>( 1/4n \cdot n^2 )</td>
<td>( 1 )</td>
</tr>
<tr>
<td>( \text{totals} )</td>
<td>( 2n^3 + n^2 )</td>
<td>( 5/4n^3 + n^2 )</td>
<td>( 1/2n^3 + n^2 )</td>
</tr>
</tbody>
</table>

The algorithm MemoryOrder uses these costs to compute a preferred loop ordering of \( (J, K, I) \), from outermost to innermost. The same result is obtained by previous researchers [AKS84, WI91].

5.2 Permuting to Achieve Memory Order

We must now decide whether the desired memory order is legal. If it is not, we must select some legal loop permutation close to memory order. To determine
whether a loop permutation is legal is straightforward. We permute the entries in the distance or direction vector for every true, anti, and output dependence to reflect the desired loop permutation. The loop permutation is illegal if and only if the first nonzero entry of some vector is negative, indicating that the execution order of a data dependence has been reversed [AK84, Ban90a, Ban90b, Wl90].

In many cases, the loop permutation calculated by MemoryOrder is legal and we are finished. However, if the desired memory order is prevented by data dependences, we use a simple heuristic for calculating a legal loop permutation near memory order. The algorithm for determining this organization takes \( \max(D, n^2) \) time in the worst-case where \( n \) is the depth of the nest and \( D \) is the number of dependences, a definite improvement over considering all legal permutations, which is exponential in \( n \). The algorithm is guaranteed to find a legal permutation with the desired inner loop, if one exists.

5.2.1 Permutation Algorithm

Given a memory ordering \( \{\sigma_1, \sigma_2, \ldots, \sigma_n\} \) of the loops \( \{i_1, i_2, \ldots, i_n\} \) where \( \sigma_1 \) has the least reuse and \( \sigma_n \) has the most, we can test if it is a legal permutation directly by performing the equivalent permutation on the elements of the direction vectors. If the result is a legal set of direction vectors, the loops are permuted accordingly.

Otherwise, we attempt to achieve a “nearby” permutation with the algorithm NearbyPermutation. The algorithm builds up a legal permutation in \( P \) by first testing to see if the loop \( \sigma_n \) is legal in the outermost position. If it is legal, it is added to \( P \) and removed from \( L \). If it is not legal, the next loop in \( L \) is tested. Once a loop \( l \) is positioned, the process is repeated starting from the beginning of \( L = \{l\} \) until \( L \) is empty. The following theorem holds for the NearbyPermutation algorithm.

**Theorem:** If there exists a legal permutation where \( \sigma_n \) is the innermost loop, then NearbyPermutation will find a permutation where \( \sigma_n \) is innermost.

The proof by contradiction of the theorem proceeds as follows. Given an original set of legal direction vectors, each step of the “for” is guaranteed to find a loop which results in a legal direction vector, otherwise the original was not legal [AK84, Ban90a]. In addition, if any loop \( \sigma_1 \) through \( \sigma_{n-1} \) may be legally positioned prior to \( \sigma_n \) it will be.

This characteristic is important because most data reuse occurs on the innermost loop and is due to spatial reuse, so positioning the inner loop correctly will yield the best data locality.

6 Parallelism

In the following two subsections, parallelism is evaluated and exploited. We first present a performance estimator that evaluates the potential benefit of parallelism. A parallel code generation strategy then uses performance estimation and the cost model developed in the previous section with other transformations to combine effective parallelism and memory order, making tradeoffs as necessary.

6.1 Performance Estimation

This section uses performance estimation to quantify the effects of parallelism on execution time. Our performance estimator predicts the cost of parallel and sequential performance using a loop model and a training set approach.

The goal of our performance estimator is to assist in code generation for both shared and distributed memory multiprocessors [BFKK92, KMM91]. Modeling the target machines at an architectural level would require calculating an analytical model for each supported architecture. Instead our performance estimator uses a training set to characterize each architecture in a machine-independent fashion. A training set is a group of kernel computations that are compiled, executed and timed on each target machine. They measure the cost of operations such as multiplication, branching, intrinsics, and loop overhead. These costs are then made available to the performance estimator via a table of data. Note, the training sets for the performance estimator only measure access times to data in registers or the closest cache.

Of particular interest is the estimation of parallel loops. Given sufficient parallel granularity, using all available processors results in the best execution time.
Interpolated contours in microseconds

Figure 5: Parallel loop training set

Estimating the cost in this circumstance may be modeled by determining the following.

\[ c_s = \text{cost of starting parallel execution} \]
\[ c_f = \text{cost of forking and synchronizing a parallel process} \]
\[ P = \text{number of processors} \]
\[ b = \text{number of iterations of the parallel loop} \]
\[ t(B) = \text{cost of the loop body} \]

If the loop bounds are unknown, a guess is used that is based on the declared dimension of the arrays accessed in the loop. With these parameters the performance of a parallel loop with sufficient work may be estimated by:

\[ c_s + c_f P + \left[ \frac{b}{P} \right] t(B) . \]

However, if the amount of work is not sufficient, parallel loop execution is more difficult to model. Instead of an equation, a table is used to indicate the appropriate number of processors for the best performance. The model and the table are generated using a training set.

The sample training set for determining parallel loop overhead begins by varying the total amount of work. For each unit of work, the number of processors is varied from 1 to the total available. The number of processors which minimize the execution time of this work is selected. The result of a training run for parallel loops on the Sequent S81 appears in Figure 5.

This particular training run repeatedly performed a single scalar operation that executed for approximately 10 microseconds, which represents one unit of work in Figure 5. Each of the contour lines indicates a particular execution time. The single line cutting across the contour lines represents the minimum execution time for executing a particular work load and the appropriate number of processors. When total work is below 250 a table determines the appropriate number of processors and approximate execution time. Once the total work is over about 250, the parallel loop model is used. The estimator provides a single cost function for evaluating loops that chooses between the techniques based on total work and number of loop iterations.

\[ \text{Estimate}(l, \text{how}) \text{ returns } (\tau, np) \text{ where} \]
\[ l \text{ is a loop with body } B \]
\[ \text{how} \text{ indicates whether } l \text{ may be run in parallel} \]

This function returns a tuple \((\tau, np)\) with an estimate \(\tau\) which is the minimal execution time and the number of processors \(np\) necessary to obtain the estimate, based on whether the loop is parallel. Note, if the loop is sequential or it is not profitable to run it in parallel, the sequential running time and \(np = 1\) are returned.

6.2 Introducing Parallelism

The key to introducing parallelism is to maintain memory order during parallelization by using strip mining and loop shifting (loop shifting moves an inner loop outward across one or more loops). Strip mining performs two functions in parallelization. (1) It preserves cache line reuse in parallel execution. Without strip mining, consecutive iterations may be scheduled on different processors, denying cache line reuse. (2) Because strip mining results in two loops, the parallel iterator loop may be shifted outward to maximize granularity while the sequential strip remains in place providing the data locality introduced using memory order. To illustrate this point, consider the subroutine \(d m x p y\) from Limpak written in memory order [DBM79].

\[ \text{DO } J = J \text{MIN}, N2 \]
\[ \text{DO } I = 1, N1 \]
\[ Y(I) = Y(I) + X(J) \times M(I,J) \]

The \(J\) loop is not parallel. The \(I\) loop can be parallel. Both contain reuse. A simple parallelization that maximizes granularity would interchange the two loops and make the \(I\) loop parallel without strip mining. Unfortunately with this organization, the parallel loop may be scheduled such that consecutive iterations are assigned to different processors causing false sharing of \(Y\) and eliminating cache line reuse for consecutive accesses to \(X\) and \(M\). In addition, cache lines containing the same array elements would be required at multiple processors, increasing total memory and bus utilization.

We instead strip mine a parallel loop by strip size \(S = \lfloor N1/np \rfloor\) to provide reuse on the strip and parallelize the resultant iterator. If the parallel loop is outermost, as in matrix multiply, parallelization is complete. If not, we use loop shifting to move the parallel iterator to its outermost legal position, maximizing its granularity. Applying this strategy to \(d m x p y\), we begin with
the memory ordered loop nest. The I loop is the only parallel loop and it contains reuse. Therefore, it is strip mined. The parallel iterator is not outermost, but it is legally shifted to the outermost position. The compiler shifts the loop, resulting in maximum granularity and data locality as illustrated below.

\begin{verbatim}
PARALLEL DO I = 1, N1, SS
   DO J = JMIN, N2
      DO II = I, MN(I + SS - 1, N1)
          Y(II) = Y(II) + X(J) * M(II, J)
      \enddo
\endverbatim

6.3 Strip Mining Algorithm

If a loop is selected to be performed in parallel, it is strip mined if it contains any reuse. Given sufficient iterations, strip mining exploits data locality and parallelism by using \([N/P]\) as the strip size where \(N\) is the number of iterations. Assuming \(ds \leq P\), the iteration space is sufficiently large if \(P < N\). If

\[
P < N < ds * P,
\]

strip mining by \([N/P]\) is less than the \(ds\) and may result in false sharing. However, the granularity of the parallel loop does match \(P\) and some reuse will occur. In this case, we still strip mine by \([N/P]\). However, if \(N < P\), strip mining may provide reuse but at the cost of drastically reducing the granularity of parallelism. This tradeoff is very machine specific. We choose not to strip mine when \(N < P\).

When memory order is computed, the loops are marked to indicate if they contain any reuse. If there is reuse, the strip mining algorithm uses the above equations to select a strip size that maximizes granularity and reuse. If there is no reuse, the strip mining algorithm does not perform strip mining, giving more flexibility to the scheduler.

6.4 Parallelization Algorithm

For memory ordered loop nests that are not parallel on the outermost loop, the Parallelization algorithm uses loop shifting to introduce parallelism. It uses loop shifting, rather than a general loop permutation algorithm, in order to minimize the effect of parallelization on data locality. It performs strip mining when the loop contains reuse before shifting for the same reason.

The algorithm for introducing parallelism into memory order appears in Figure 6. It begins by testing whether the outermost loop is parallel. In the first iteration of the “for \(k\)” \((j = k = 1)\), the first “if” tests if the outermost loop is parallel. Trivially, a shift of loop \(\sigma_j\) to position \(j\) is always legal.

If the loop is parallel, it is strip mined and parallelized and the algorithm returns. If the loop is not parallel, a legal shift of an inner loop to position \(j\) which is parallel at position \(j\) is sought. If a parallel loop is found that can be shifted outermost to \(j\), it is strip mined, parallelized and shifted and the algorithm returns. Otherwise, a shift to position \(j\) may cause the next inner loop, i.e., the loop originally positioned at \(j\), to be parallel. This situation is determined in the “else.” Because it is more desirable to parallelize a loop at position \(j\) than at \(j + 1\), all other shifts to position \(j\) are considered before this parallelization is returned at the completion of the “for \(k\).”

In Figure 6 the Parallelize algorithm does not detect when strip mining results in a strip size of less than \(ds\) or strip mining is not performed due to insufficient parallel iterations. As we saw in Section 3, these conditions are unavoidable in some cases and the best possible performance is gained even when they hold. However, we extend Parallelize as follows to seek a better parallelization for which neither condition holds.

If StripMine returns with a strip size of less than \(ds\) or does not strip mine due to insufficient parallel iterations, then the number of parallel iterations \(P_i\) and the size of the strip \(SS\) are recorded and the “for \(k\)” loop continues instead of returning. If the “for \(k\)” finds a parallelization where neither condition holds, it returns. Otherwise, at the completion of the “for \(k\)” it selects the parallelization with the largest pair \((P_i, SS)\).

7 Optimization Algorithm

The optimization driver for exploiting data reuse and introducing parallelism appears in Figure 7. It combines the component algorithms described in the previous sections and is also \(O(n^2)\) time.

It first calls MemoryOrder to optimize data locality via loop permutation. It then determines whether the loop contains sufficient computation to pursue parallelism. If it does, the memory ordered loop nest is provided to the algorithm Parallelize. If needed, Parallelize uses strip mining and loop shifting to introduce loop level parallelism.
Figure 7: Algorithm Optimizer

INPUT: \( L = \{b_1, \ldots, b_n\} \)
OUTPUT: \( T \) an optimization of \( L \)

ALGORITHM:
\[ O = \text{MemoryOrder}(L) \]
\[ np = \text{Estimate}(O, \parallel) \]
if \( np > 1 \) (parallelism is profitable)
\[ T = \text{Parallelize}(O) \]
endif
perform \{ \( O, T \) \}

The search space in \texttt{Parallelize} is constrained to meet our goal of perturbing the memory order as little as possible. If parallelism is not discovered and would be profitable, other optimization strategies that consider all loop permutations, loop skewing [WL90], or loop distribution [McK92] should be explored.

8 Experimental results

We tested the algorithm for optimizing data locality independently and report some of these results here. The overall parallelization strategy was also tested by applying it by hand to several kernels and to the program Erlebacher, provided by Thomas Ekdon from ICASE. The results of these experiments are very promising.

8.1 Matrix multiply

We executed all possible loop permutations of matrix multiply for three problem sizes, \( 150 \times 150, 300 \times 300 \) and \( 512 \times 512 \), on a variety of uniprograms to determine the accuracy of the \texttt{MemoryOrder} in predicting the best loop permutations. In Table 1, the permutations are ordered from the most desirable to the least based on the ranking computed by \texttt{MemoryOrder}. On most of the processors, memory order \texttt{JKI} produced the best results. On all the processors but the \texttt{Sequent}, the entire ranking generally served to accurately predict relative performance. These results illustrate that \texttt{LoopCost} is effective in predicting relative reuse on outer loops as well as inner loops.

Interestingly, the disparity in execution times between permutations became greater as the processor speed increased. On the individual processors, execution times varied by significant factors of up to 3.69 on the Sparc2, 6.25 on the i860, and a dramatic 23.89 on the RS6000. These results indicate that data locality \textit{should} be the overwhelming force driving scalar compilers today.

The speed-ups of a parallel tiled matrix multiply on 19 processors of a Sequential Symmetry 881 for arrays of size \( 150 \times 150 \), \( 300 \times 300 \) and \( 512 \times 512 \) are presented in Table 2. We ran a sequential version with the loops in memory order \texttt{JKI}, a sequential tiled version, and the identically tiled parallel version. The parallel version is tiled by 4 and is the same version presented in Section 1.1. Besides tiling, no other low-level memory optimizations were used. The speed-ups were basically linear for both matrix sizes when comparing the two tiled versions.

8.2 \texttt{Dmxpy}

The subroutine \texttt{Dmxpy} from Linpack was optimized using these algorithms as illustrated in Section 6.2. In scientific programs, there are many instances of this type of doubly-nested loop which iterates over vectors and/or matrices, where only one loop is parallel and it is best ordered at the innermost position. These loops may be an artifact of a vectorizable programming style. They appear frequently in the Perfect benchmarks [CKPK90], the Level 2 BLAS [DCHH88], and the Livermore loops [McM86].

Table 3 illustrates the performance benefits with the organization of \texttt{Dmxpy} generated by our algorithm on matrices of size \( 200 \times 200 \) on 19 processors. For comparison, the performance when the 1 strip is not returned to its best memory position and a parallel inner 1 loop were also measured.

8.3 Erlebacher

Erlebacher is a tri-diagonal solver for the calculation of variable derivatives written by Thomas Eidson at ICASE, NASA-Langley. It uses 3 dimensional $64 \times 64 \times 64$ arrays. It contains 1341 lines of Fortran. The Optimizer algorithm was performed by hand on the entire program. No low-level memory optimizations were performed. The speed-up from this algorithm on 19 processors was 14.2 for the entire application. The speed-up for the parallel portions of the program was 15.0.

9 Related work

Our work bears the most similarity to research by Wolf and Lam [WL91]. They develop an algorithm that estimates all temporal and spatial reuse for a given loop permutation, including reuse on outer loops. This reuse is represented as a localized vector space. Vector spaces representing reuse for individual and multiple references are combined to discover all loops $L$ carrying some reuse. They then exhaustively evaluate all legal loop permutations where some subset of $L$ is in the innermost position, and select the one with the best estimated locality.

Wolf and Lam’s algorithm for selecting a loop permutation is potentially more precise and powerful than the one presented in this paper. It directly calculates reuse across outer loops and can suggest loop skewing and reversal to achieve reuse; however, how often these transformations are needed is yet to be determined. Skewing in particular is undesirable because it reduces spatial reuse.

Gannon et al. also formulate the dependence testing problem to give reuse and volumetric information about array references [GJG88]. This information is then used to tile and interchange the loop nests for cache, after which parallelism is inserted at the outermost possible position. They do not consider how the parallelism affects the volumetric information nor if interchange would improve the granularity of parallelism.

Porterfield presents a formula that approximates the number of cache lines accessed, but is restricted to a cache line size of one and loops with uniform dependences [Por89]. Ferrante et al. present a more general formula that approximates the number of cache lines and is applicable across a wider range of loops [FST91]. However, they first compute an estimate for every array reference in a loop nest and then combine them, trying not to do dependence testing. Like Wolf and Lam, they exhaustively search for a loop permutation with the lowest estimated cost.

Many algorithms have been proposed in the literature for introducing parallelism into programs. Callahan et al. use the metric of minimizing barrier synchronization points via loop distribution, fusion and interchange for introducing parallelism [ACK87, Cal87]. Wolf and Lam [WL90] introduce all possible parallelism via the unimodular transformations: loop interchange, skewing, and reversal. Neither of these techniques try to map the parallelism to a machine, or try to take into account data locality, nor is any loop bound information considered. Banerjee also considers introducing parallelism via unimodular transformations, but only for doubly nested loops [Ban90b]. Banerjee does however consider loop bound information.

Because we accept some imprecision, our algorithms are simpler and may be applied to computations that have not been fully characterized in Wolf and Lam’s unimodular framework. For instance, we can support imperfectly nested loops, multiple loop nests, and imprecise data dependences. We believe that this approximation is a very reasonable one, especially in view of the fact that we intend to use a scalar cache tiling method as a final step in the code generation process [CKK90]. In addition, the algorithms presented here are $O(n^2)$ time in the worst case, where $n$ is the depth of the loop nest, and are a considerable improvement over work which compares all legal permutations and then picks the best, taking exponential time.

10 Summary and Conclusions

We have addressed the problem of choosing the best loop ordering in a nest of loops for exploiting data locality and for generating parallel code for shared-memory multiprocessors. As our experimental results bear out, the key issue in loop order selection is achieving effective use of the memory hierarchy, especially cache lines. Our approach improves data locality, provides the highest granularity of parallelism, and properly positions loops for low-level memory optimizing transformations. When possible, the benefits of parallelism and data locality are therefore both exploited.

We believe our experimental results provide strong evidence for the effectiveness of this approach. With this method, the programmer is permitted to pay more attention to the correctness of a calculation and less to the explicit loop structure required to achieve high performance.

Acknowledgments

We are especially grateful to Chun-Wen Tseng for his significant contributions to this work. We would like to thank Preston Briggs, Cliff Click, Ervan Darnell, and Nathaniel McIntosh for their many helpful discussions and experiments. We also appreciate the constructive detailed suggestions from one of our reviewers.
