**A Population Gain Control Model of Spatiotemporal Responses in  
the Visual Cortex**

by

**Yiu Fai Sit, B.Eng.; M.Phil.**

**Dissertation**

Presented to the Faculty of the Graduate School of

The University of Texas at Austin

in Partial Fulfillment

of the Requirements

for the Degree of

**Doctor of Philosophy**

**The University of Texas at Austin**

August 2009

# Acknowledgments

This dissertation would not have been possible without the guidance and support of my advisers, Eyal Seide-mann and Risto Miikkulainen. Eyal is an outstanding mentor and scientist. I could not have accomplished what I did without his insightful suggestions, critical comments, and excellent advice throughout this research. Risto has been a constant source of encouragement, inspiration, and motivation during my whole graduate career. My interest in computational neuroscience finds deep roots in his work and this dissertation would not even have started without his introduction to this field.

A special thank you must go to Bill Geisler. Bill is one of the pioneers who laid the foundation of this work. I am grateful for his invaluable ideas and feedback throughout this research, not to mention all the improvements that he made in the revisions of our paper.

I would also like to thank all the friends and colleagues in Eyal's and Risto's labs for their discussions, comments, and questions, especially Yuzhi Chen and Bill Bosking. Yuzhi did all the experiments with the monkeys described in the first half of this dissertation and has contributed many ideas to my work. The lateral interactions experiments were done by Bill, who had provided many helpful comments and advice on various projects. I also thank Zhiyong Yang for collecting the data for the moving stimuli.

I thank my wonderful family for their support throughout my study. I am very fortunate to have a loving family and I am grateful for all their faith and trust in me. Finally, I thank my wife, Yoe, for her love and patience that keep this long-distance relationship lively and fresh.

Supervisors: Risto Miikkulainen, Eyal Seidemann

The mammalian brain is a complex computing system that contains billions of neurons and trillions of connections. Is there a general principle that governs the processing in such large neural populations? This dissertation attempts to address this question using computational modeling and quantitative analysis of direct physiological measurements of large neural populations in the monkey primary visual cortex (V1). First, the complete spatiotemporal dynamics of V1 responses over the entire region that is activated by small stationary stimuli are characterized quantitatively. The dynamics of the responses are found to be systematic but complex. Importantly, they are inconsistent with many popular computational models of neural processing. Second, a simple population gain control (PGC) model that can account for these complex response properties is proposed for the small stationary stimuli. The PGC model is then used to predict the responses to stimuli composed of two elements and stimuli that move at a constant speed. The predictions of the model are consistent with the measured responses in V1 for both stimuli. PGC is the first model that can account for the complete spatiotemporal dynamics of V1 population responses for different types of stimuli, suggesting that gain control is a general mechanism of neural processing.

# Chapter 1

## Introduction

The mammalian brain is a complex computing system. It contains billions of neurons, each of which is a nonlinear computing unit that connects with thousands of neurons. Such complexity is fascinating, but at the same time it makes understanding the brain one of the hardest problems in science. Are there general principles for the computation in the brain? Is it even possible to find one?

The goal of this dissertation is to uncover such a principle for how large neural populations, such as the primary visual cortex (V1), respond to canonical stimuli. In order to do that, empirical measurements of responses in V1 will be combined with computational simulations. The result will be a computational theory that can be used to understand processing at the population level in many areas of the cortex.

### 1.1 Motivation

The traditional approach to understand neural processing is to study the individual components of the brain, i.e. single neurons. By observing the change in response as some feature in the stimulus varies, the computation performed by the neuron can be characterized. However, given the interconnected nature of the brain, a neuron's response is hardly due to the stimuli alone. Any neuron that connects to it, directly or indirectly, can affect its response. A neuron's response is therefore only a part of the computation carried out by a large neural population. Single-unit responses can therefore only provide a partial picture of the processing in the brain.

A more appropriate approach to study neural computation is to measure the responses of a large population of neurons simultaneously and directly. Although population responses can potentially be estimated from the results of single-unit recordings, neurons are interconnected and vastly heterogeneous. It is thus unclear how these properties are combined and manifested at the population level. In addition, population responses need to be measured at high spatial and temporal resolution to capture their dynamics accurately. For instance, hemodynamic responses measured by fMRI and intrinsic optical imaging are too slow for characterizing the dynamics. However, optical imaging can be combined with voltage-sensitive dyes, achieving temporal resolution at the millisecond range. The first main contribution of this dissertation is to use such voltage-sensitive dye imaging (VSDI; Grinvald & Hildesheim, 2004) to provide the first complete quantitative description of the dynamics of population responses for simple stimuli.

Based on the population responses, it is then possible to search for the general principles of computation in the brain. A computational model is a formal hypothesis of how the observed response dynamics arise. If the hypothesis reflects a general mechanism, its predictions should be consistent with the neural

responses for a variety of stimuli. For instance, the Hodgkin-Huxley model (Hodgkin & Huxley, 1952) is highly successful in this regard. It explains and predicts the dynamics of an individual neuron accurately (De Schutter & Bower, 1994a, 1994b; Mainen & Sejnowski, 1998), setting the standard for what a computational model should accomplish. However, as in traditional studies of neural responses, the Hodgkin-Huxley model and its extensions apply only to a single neuron or a few neurons. They are not as effective for a large neural population, because they require a large number of parameters.

To understand the processing of a neural population, models with a higher level of abstraction are required. However, in contrast to the Hodgkin-Huxley model, most large-scale models of neural populations either do not take the response dynamics into account (Miikkulainen, Bednar, Choe, & Sirosh, 2005; Sit & Miikkulainen, 2009), or ignore some of the nonlinearities of the response (Ben-Yishai, Bar-Or, & Sompolinsky, 1995; Somers, Nelson, & Sur, 1995; Hansel & Sompolinsky, 1998). A new class of computational models that operates at the population level and takes the response dynamics and nonlinearity into account is therefore needed to understand processing at the population level in the brain. The second main contribution of this dissertation is to provide such a model. The aim is to create a standard model for neural populations, similar to what the Hodgkin-Huxley model is of single neurons.

## 1.2 Approach

To provide the foundation for the model, VSDI is used in this dissertation to measure population responses in the macaque primary visual cortex (V1) from the entire spatial region of activity at high spatial and temporal resolution for brief, localized stimuli. The spatiotemporal dynamics of these responses are thus quantitatively characterized for the first time.

Next, this dissertation considers whether there is a general mechanism that can account for the dynamics of V1 population responses over the entire active region. Different computational models that have been proposed in the past are tested using the stimuli in the VSDI experiment as input. Most of them are found to be inconsistent with the observed response properties.

To account for the observed properties in both time and space, this dissertation then proposes a population gain control (PGC) model that generalizes earlier normalization models for single neurons in the LGN (Shapley & Victor, 1978; Victor, 1987; Bonin, Mante, & Carandini, 2005) and V1 (Albrecht & Geisler, 1991; Heeger, 1992; Carandini, Heeger, & Movshon, 1997; Mante, Bonin, & Carandini, 2008). The early visual pathway, i.e. from the retina to V1, is simulated with the PGC model using the stimuli in the VSDI experiments, and the model is validated by comparing the spatiotemporal dynamics of the simulated responses and VSDI responses.

To investigate if population gain control is a general mechanism, two further experiments are performed. In the first experiment, the PGC model is applied to stimuli consisting of two elements. The contrast of each element and the separation between them are varied systematically. The model predicts that certain stimuli have a strong effect on the responses due to the interactions between the two elements. These stimuli are then used in further VSDI experiments, validating the model.

In the second experiment, stimuli containing an element that moves around in visual space are used. Such stimuli provides a challenging test because the visual pattern changes in both time and space, whereas the PGC model is developed based on the responses for brief, localized stimuli.

### 1.3 Outline of the dissertation

This dissertation is organized into three main parts: background (Chapters 1-3), results (Chapters 4-7), and discussion (Chapters 8-9).

**Chapter 2** provides the background on the anatomical and physiological properties of the early visual pathway that are relevant for computational models of neural populations. It also introduces voltage-sensitive dye imaging (VSDI), the technique that was used to measure the population responses in this dissertation.

**Chapter 3** reviews previous computational models of single neurons in V1 and the ways in which they have been applied to model a large population of neurons. Specific predictions are then drawn from these models on the properties of population responses.

**Chapter 4** provides the quantitative characterization of the spatiotemporal dynamics of the VSDI responses in V1 for a brief, localized visual stimulus. The predictions of the models reviewed in Chapter 3 are compared with the data and found to be largely inconsistent with the data. Also, the model is used to address the outstanding question regarding the degree to which nonlinearities in V1 responses are inherited from its inputs. Results of the model and further VSDI experiments suggest that most of the normalization occurs before the superficial layers of V1.

**Chapter 5** introduces the PGC model, specifies its definition mathematically, and analyzes its dynamics for the stimuli used in Chapter 4. Simulation results of the model are compared with the VSDI responses and shown to be consistent with the data.

**Chapter 6** presents predictions of the model for stimuli consisting of two elements, and compares them with the VSDI responses. It shows that for different combinations of element contrasts and separation, the model's predictions are consistent with the properties of the VSDI responses.

**Chapter 7** presents simulation results with moving stimuli and compares the model's prediction with the VSDI responses. The model's predictions agree with the VSDI responses, suggesting again that population gain control is a general mechanism of visual processing.

**Chapter 8** discusses how the PGC model can be extended to a finer spatial scale to incorporate orientation-specific signals. It also proposes future research directions of the extended model: (1) analysis of the network's stability, (2) study of the neural code for orientation, (3) investigation of its impact on developmental models, and (4) simulation of high-level areas.

**Chapter 9** concludes the dissertation by reviewing its contributions.

# Chapter 2

## Background

The anatomical and physiological properties of the early visual pathway that are relevant for computational models of neural populations are reviewed in this chapter and the reasons why population responses are important in understanding visual processing are summarized. This chapter also describes voltage sensitive dye imaging (VSDI), the technique that was used to measure population responses in this dissertation. Finally, the shortcomings of applying detailed biophysical models for such responses are reviewed, motivating a new computational model.

### 2.1 The early visual pathway

This section provides a brief review of the early visual pathway in primates (Figure 2.1), with emphasis on the properties that are relevant for computational models of neural populations. For a more detailed review, see e.g. Kandel, Schwartz, and Jessell (2000) and Wandell (1995).

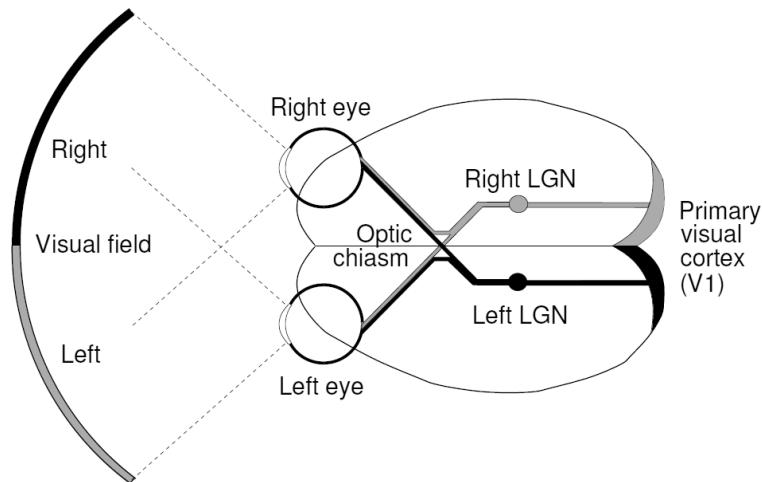

#### 2.1.1 Retina

Light from the environment passes through the lens of the eye and impinges on the retina, which contains an array of photoreceptors and other related cells. The responses of the photoreceptors are connected to a network of bipolar cells, horizontal cells, amacrine cells, and retinal ganglion cells. Horizontal cells and amacrine cells connect to other cells laterally, thus providing a substrate for integrating responses from a wider space. The retinal ganglion cells are the output of this network. An On-center retinal ganglion cell responds most strongly to a spot of light surrounded by a dark region at a particular location of the visual space (Figure 2.2a). Such a pattern, including its location, is called the receptive field of the cell. Similarly, an OFF-center ganglion cell prefers a dark spot surrounded by a light region (Figure 2.2b). Such center-surround receptive field is most sensitive to changes in local luminance, i.e. contrast.

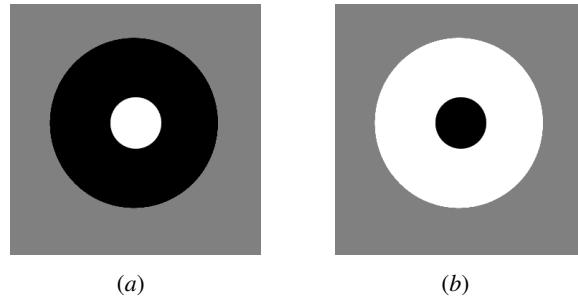

The responses of the retinal ganglion cells pass through the optic nerve to the optic chiasm, where the signals from the left and right visual fields split: The visual responses for the left visual field from both eyes are routed to the right hemisphere of the brain, and vice versa (Figure 2.1).

#### 2.1.2 Lateral geniculate nucleus (LGN)

From the optic chiasm, signals of the same visual field reach the lateral geniculate nucleus (LGN) in the thalamus on the contralateral side. Neurons in the LGN have similar properties to the retinal ganglion cells.

**Figure 2.1: The early visual pathway.** Light entering the eye is transduced into spiking activity in the retina. Visual information about the left visual field from both eyes (gray) join at the optic chiasm and travel to the primary visual cortex (V1) on the right hemisphere through the lateral geniculate nucleus (LGN) in the right thalamus. Similarly, information about the right visual field is routed to the left hemisphere. Signals from each eye are kept segregated in the LGN, but combined in V1. Within each stage, there are also substantial interactions among the neurons. Figure adapted from Miikkulainen et al. (2005).

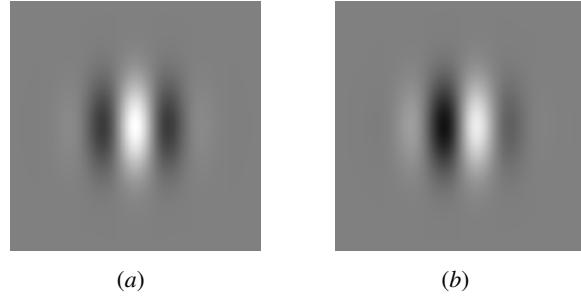

**Figure 2.2: Receptive fields of the retinal ganglion cells and LGN cells.** (a) ON cells prefer light spot surrounded by dark region. (b) OFF cells have the opposite preferences. The receptive fields are localized, i.e. stimulus falling in the gray region does not elicit a response. Such a center-surround receptive field is most sensitive to local contrast.

The receptive fields of LGN cells are also arranged retinotopically, so that nearby cells respond to nearby portions of the retina. In addition, there are inhibitory interneurons in the LGN that receive inputs from the retina directly and provide feedforward inhibition to the LGN cells (Sillito & Kemp, 1983; Norton & Godwin, 1992). There are also feedback connections from the cortex (Murphy & Sillito, 1996; Ichida & Casagrande, 2002; Angelucci & Sainsbury, 2006). Although the exact roles of the feedforward inhibition and feedback connections are unclear, they are likely to carry signals from regions outside the receptive fields of the target cells and affect their responses.

### 2.1.3 Primary visual cortex (V1)

The primary visual cortex (V1) receives direct input from the LGN. It is the first cortical area of visual processing (the retina and LGN are subcortical). Like the LGN, V1 has a retinotopic organization.

The neurons in the primate cortex are arranged in six layers (Henry, 1989). Input from the LGN typ-

**Figure 2.3: Spatial receptive fields of V1 neurons.** (a) A receptive field with vertical orientation and a  $0^\circ$  phase. (b) A vertical receptive field with a  $90^\circ$  phase. The receptive fields are selective to the orientation, phase, and spatial frequency of the stimulus. Stimuli deviating from the optimal values elicit weaker response, resulting in a tuning curve for each of these parameters.

ically terminates in layer 4 (Casagrande & Norton, 1989). The layers above layer 4, which are closer to the surface of the cortex, are collectively called the superficial layers, and those below it, the deep layers. Neurons in the superficial and deep layers form intracortical connections within V1 and intercortical connections with other visual areas. For instance, many neurons in layers 2 and 3 have long-range intracortical lateral connections to the surrounding neurons in V1 (Fisken, Garey, & Powell, 1975; Gilbert & Wiesel, 1979, 1983; Hirsch & Gilbert, 1991; Bosking, Zhang, Schofield, & Fitzpatrick, 1997; Angelucci, Levitt, Walton, et al., 2002). These lateral connections are usually not myelinated and have a slow conduction speed of 0.1-0.4 mm/ms (Hirsch & Gilbert, 1991; Murakoshi, Guo, & Ichinose, 1993; Grinvald, Lieke, Frostig, & Hildesheim, 1994; Nelson & Katz, 1995; González-Burgos, Barrionuevo, & Lewis, 2000; Telfeian & Connors, 2003). There are also extensive feedback connections from higher level areas (Felleman & Van Essen, 1991; Salin & Bullier, 1995; Angelucci, Levitt, Walton, et al., 2002), which are much faster than the lateral connections ( $\sim 3.5$  mm/ms; Girard, Hupe, & Bullier, 2001). Although the roles of lateral and feedback connections in visual processing are still largely unknown, these connections convey information about a large visual space to the neurons that they contact.

Many of the V1 neurons are selective, or tuned, to the orientation of the stimulus, i.e. they fire most rigorously for a particular orientation and less for others. A common model for the V1 receptive field is the Gabor pattern (Daugman, 1980; Jones & Palmer, 1987), which is an oriented sinusoid with a Gaussian envelope (Figure 2.3):

$$\exp\left(-\frac{x^2}{2\sigma_x^2} - \frac{y^2}{2\sigma_y^2}\right) \cos(2\pi f x + \psi), \quad (2.1)$$

where

$$x = x' \cos \theta + y' \sin \theta \quad (2.2)$$

$$y = -x' \sin \theta + y' \cos \theta. \quad (2.3)$$

The last two equations rotate the axes by  $\theta$ , which specifies the orientation of the Gabor function. In the first equation,  $\sigma_i$  is the width of the Gaussian along the rotated  $i$ -axis,  $f$  is the spatial frequency, and  $\psi$  is the phase of the sinusoid. Such a receptive field could be constructed by an alignment of ON- and OFF-center LGN cells that reflects the preferred orientation of the V1 neuron (Hubel & Wiesel, 1962, 1968), and a Gaussian input weight for the envelope.

The curve that plots the neuron's response as a function of orientation is called the tuning function. The tuning function is unimodal, i.e. there is only one preferred orientation. One common way to characterize sharpness of tuning is by half-bandwidth, which is half the difference between the orientations that elicit  $1/\sqrt{2}$  of the peak response on the two sides of the preferred orientation (Schiller, Finlay, & Volman, 1976). The half-bandwidth of orientation tuning in monkey V1 neurons is about  $25^\circ$  (Schiller et al., 1976; De Valois, Yund, & Hepler, 1982; Ringach, Shapley, & Hawken, 2002). One interesting property that seems to be universal in V1 cells is that the shape of the orientation tuning curve is contrast-invariant: Changing the contrast of the stimulus only scales the tuning curve but its shape is not affected (Skottun, Bradley, Sclar, Ohzawa, & Freeman, 1987; Albrecht & Geisler, 1991; Sclar & Freeman, 1982).

The neurons in a vertical column through the six layers of V1 have similar preferences for visual stimuli (Hubel & Wiesel, 1962, 1977). Many computational models of V1 take advantage of such a columnar organization and represent the cortex as a sheet of neurons instead of a three-dimensional structure. Interestingly, for neighboring columns in V1, the orientation-preference changes gradually, with their receptive fields at similar visual locations. Such an organization leads to the concept of hypercolumns, which contain the full set of receptive field parameters at a single location in the visual space. The average receptive field of a hypercolumn can therefore be treated as the Gaussian envelope of the Gabor receptive fields of its constituent columns, an approximation used in this dissertation to model the responses of a local neural population in V1.

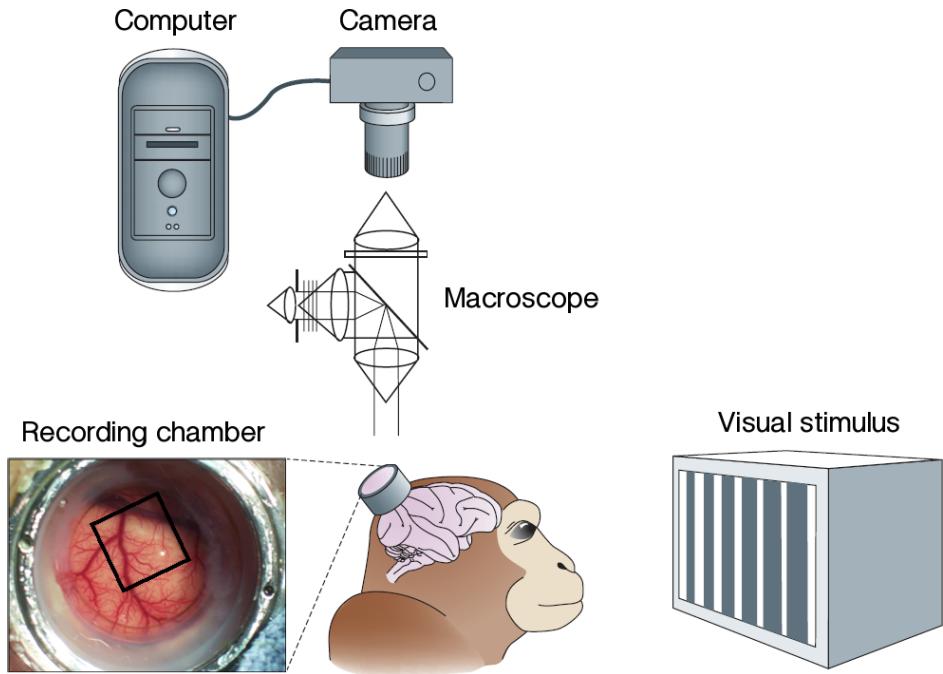

## 2.2 Population responses in V1

As discussed above, single neurons are broadly tuned. A small visual stimulus can therefore elicit responses in a substantial population of V1 neurons even though it is not the preferred stimulus for most of these neurons. Are these responses for non-preferred stimuli useful for perception? Electrophysiological studies in behaving primates and computational analysis of neural responses suggest that perceptual responses are in fact mediated by populations of neurons that have a variety of stimulus preferences (Shadlen, Britten, Newsome, & Movshon, 1996; Parker & Newsome, 1998; Purushothaman & Bradley, 2005). Population coding has also been proposed as the representation of movement direction in motor neurons (Georgopoulos, Schwartz, & Kettner, 1986), suggesting that it is a general mechanism in the brain. Thus, to understand the encoding and decoding of visual stimuli in the cortex, it is important to characterize the properties of V1 population responses.

One approach to estimate population responses is by combining electrophysiological measurements of single neuron responses. However, neurons are vastly heterogeneous, and it is unclear how these properties are combined and manifested at the population level. In addition, single-unit and multiple-unit electrophysiological studies in V1 focus mainly on responses at or near the center of the activity produced by the stimulus. Responses at more peripheral locations are largely unknown. It is therefore necessary to measure population responses over a large region of the cortex directly to characterize them accurately. Next, the technique that was used in this dissertation to measure the V1 population responses is described.

## 2.3 Voltage-sensitive dye imaging (VSDI)

Optical imaging is a technique that monitors neural activity across several square centimeters of cortex (Figure 2.4). A camera is mounted over a recording chamber that allows direct visualization of the brain, and

**Figure 2.4: Voltage-sensitive dye imaging with an awake and behaving monkey.** Part of the skull of a macaque monkey was removed by surgery and the brain was covered with an artificial dura, making the surface of V1 visible through the recording chamber. A voltage-sensitive dye is applied to the exposed area that transduces changes in membrane voltage into changes in fluorescence, which are recorded with a video camera. A typical imaged area of about  $10 \times 10$  mm is indicated by the black square. The acquired images are digitized and stored in a computer for offline analysis. This technique allows recording population responses at high spatiotemporal resolution over a large area in an awake behaving animal, which is important for accurate measurement and characterization of such responses. Figure modified from Grinvald and Hildesheim (2004), with permission.

changes of reflectance of the cortical surface are observed. Voltage-sensitive dye imaging (VSDI; Grinvald & Hildesheim, 2004) is an extension of this technique that measures the changes in electrical neural activity directly by utilizing special fluorescent dyes (Grinvald et al., 1999; Shoham et al., 1999). When the dye solution is applied topically to the brain, the dye molecules penetrate the tissue and bind to cellular membranes. In the membrane, the dye molecules transduce changes in membrane voltage into changes in fluorescence. Early *in vitro* studies showed that the dye signal is directly proportional to membrane voltage (Salzberg, Davila, & Cohen, 1973; Grinvald, Salzberg, & Cohen, 1977). When applied to the cortex, the dye signals represent the sum of all changes in membrane voltage in a small volume of cortex, i.e. the aggregate activity of a local neural population of all cell types. Because the surface area of dendrites is much larger than the surface area of cell bodies, dye signals are likely to emphasize subthreshold membrane potential in dendritic arborizations. In addition, due to the opacity of the tissue, dye signals are dominated by the activity in the superficial layers of the cortex.

The main advantage of VSDI over other imaging techniques is that it measures electrical signals directly, which is important for two reasons. First, there is no need to make assumptions regarding the link between electrical activity and indirect measurements, such as hemodynamic responses in intrinsic optical imaging and fMRI. Second, VSDI signals have high spatial (microns) and temporal (millisecond) resolutions, which is important in measuring and characterizing population responses accurately. Such a direct, high-resolution measurement of population responses is not possible otherwise, and therefore new

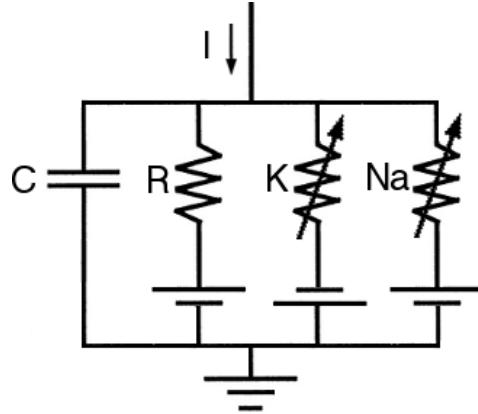

Figure 2.5: **The Hodgkin-Huxley model.** The figure shows the electrical circuit interpretation of the model. The cell membrane acts as a capacitor ( $C$ ). The voltage  $V$  across the capacitor can be changed by the input current  $I$  or by the currents that pass through the resistors, each representing a different ion channel. The battery associated with each resistor represents the reversal potential of the ion, which is the voltage caused by the different ion concentrations between the interior of the cell and its surrounding liquid at equilibrium.

insights can be gained from the spatiotemporal dynamics of these responses. This dissertation provides the first full quantitative analysis of the dynamics of population responses to small, briefly presented stimuli.

## 2.4 Hodgkin-Huxley model

Given the population responses recorded in VSDI experiments, is there a model that can describe their dynamics? This section briefly reviews the popular Hodgkin-Huxley (H-H) model and discusses its shortcoming in explaining the dynamics of a large neural population.

The Hodgkin-Huxley model of the neural membrane (Hodgkin & Huxley, 1952) was devised more than 50 years ago and is still the gold standard of low-level computational models of the brain. It provides an elegant and accurate explanation of spike generation in the membrane. The H-H model is a set of coupled differential equations that describe how the voltage  $V$  of a short membrane segment is related to the membrane current  $I$  and the dynamics of other voltage-dependent currents in different ion channels (Figure 2.5; see Rinzel & Ermentrout, 1998; Gerstner & Kistler, 2002 for detailed analyses):

$$C \frac{dV}{dt} = I(t) - g_K n^4 (V - V_K) - g_{Na} m^3 h (V - V_{Na}) - g_L (V - V_L), \quad (2.4)$$

where  $C$  is the fixed capacitance of the membrane,  $V_i$  is the reversal potential of the ion channel  $i$ , and  $g_i$  is the conductance of the resistor. Three ion channels are included in the original H-H model: potassium (K), sodium (Na), and an unspecific leakage channel (L) that mainly consists of chloride ions that pass through the resistor  $R$  (Figure 2.5). The potassium and sodium channels are not static and are controlled by the gating variables  $n$ ,  $m$ , and  $h$  that evolve according to the differential equations

$$\frac{dn}{dt} = \alpha_n(1 - n) - \beta_n n \quad (2.5)$$

$$\frac{dm}{dt} = \alpha_m(1 - m) - \beta_m m \quad (2.6)$$

$$\frac{dh}{dt} = \alpha_h(1 - h) - \beta_h h, \quad (2.7)$$

where  $\alpha$  and  $\beta$  are empirical functions (not shown) of  $V$  that are designed to fit the data of the squid giant axon in the study of Hodgkin and Huxley.

By connecting many of these short segments (compartments), each represented by the coupled differential equations 2.4 - 2.7, a detailed model of an individual neuron can be built that takes into account the morphology and the different types of ion channels and synapses of that neuron. With suitable parameters, such model can provide an accurate fit to the behavior of single neurons (De Schutter & Bower, 1994a, 1994b; Mainen & Sejnowski, 1998).

Although the H-H model is instrumental in understanding the behavior of individual neurons, it is not as effective for a large neural population, because it requires a large number of parameters. A neuron is usually modeled by linking thousands of compartments, each with its own set of parameters. The large parameter space makes it difficult to gain insight into the nature of population and on the key parameters that govern the observed behaviors (Meunier & Segev, 2002).

In order to understand the response dynamics of a neural population, models with a different level of abstraction are required. An ideal model would provide an accurate and compact description of the population response dynamics, leading to new insights into how such dynamics emerge (as the insight provided by the H-H model for the understanding of single neuron dynamics). This dissertation is an initial attempt to devise one such model.

## 2.5 Conclusion

Because perception is likely to be mediated by a group of neurons, it is important to understand the properties of population responses through physiological experiments and computational modeling. However, established biophysical models are not suitable for such a study. In the next chapter, computational models at the levels of single neurons and population of neurons will be reviewed and analyzed. This analysis leads to a new model (proposed in Chapter 5) aims at being an H-H model of population responses.

# Chapter 3

## Related Work

This chapter reviews previous computational models of single neurons in V1 and ways in which they have been applied to model a sheet of neurons. Specific predictions about the properties of membrane potential in these models are discussed; these predictions will be compared to the results of VSDI experiments in the next chapter.

### 3.1 Motivation

In general, processing in a model neuron consists of two steps: (1) inputs from different sources are combined to produce the membrane potential of the unit, and (2) a function is applied to the membrane potential to generate the spiking response of the unit; this function is usually a sigmoid or a rectifying function with a threshold. Different computational models can be classified according to how the inputs are combined in the first step. Such a classification allows direct comparison with the VSDI responses, which is dominated by subthreshold membrane potential. Three common classes of models are reviewed in this chapter: models with linear instantaneous summation, models that integrate input over time, and models with gain control on the input.

### 3.2 Models with linear instantaneous input summation

In this section, models that combine the instantaneous input linearly to compute the membrane potential are reviewed (Figure 3.1). Although such models can account for certain steady-state properties of neural responses, as will be discussed, they do not account for the temporal properties of the neural responses.

#### 3.2.1 Linear-nonlinear (LN) models

The simplest model for V1 neurons is the linear-nonlinear (LN) model, which is based on firing rates (Figure 3.1). The linear stage of the model unit computes the membrane potential as a weighted sum of input in its receptive field. After that, a static saturating nonlinearity is applied to the potential to produce the firing rate of the unit.

A popular saturating nonlinearity for neural responses is the Naka-Rushton equation (Naka & Rush-

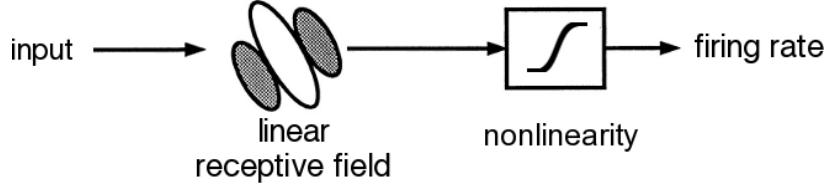

Figure 3.1: **Models with instantaneous linear summation of input.** The membrane potential of a unit is a linear summation over the receptive field on the input stimulus. The sum then passes through a static nonlinearity to transform membrane potential into a firing rate. The whole process happens instantly, i.e. the temporal dynamics of the output are completely determined by the input stimulus. This model can represent the steady-state response of a neuron efficiently, which is useful for simulating large population of neurons.

ton, 1966):

$$\frac{V^n}{V^n + V_{50}^n}, \quad (3.1)$$

where  $V$  is the membrane potential of a unit,  $V_{50}$  is a constant that corresponds to the half-saturation point, and  $n$  controls the steepness of the function around  $V_{50}$ . This function has been widely used to fit the contrast response function of neurons in the LGN and V1 (Albrecht & Hamilton, 1982; Sclar, Maunsell, & Lennie, 1990).

These models ignore the temporal integration in neurons; the membrane potential is an instantaneous function of the inputs. In other words, the temporal dynamics of the V1 membrane potential is the same as those of its inputs, i.e. subcortical responses, which is unlikely to be the case in the brain because there is significant low-pass filtering between the subcortical and V1 responses (Hawken, Shapley, & Grosof, 1996).

### 3.2.2 Push-pull effect of excitation and inhibition

In general, the LN model does not take into account the fact that neurons can receive both excitatory and inhibitory inputs from the same point in the receptive fields. More realistic models that include such inputs can therefore reconcile some of the inconsistencies between the LN model and the neural responses. For instance, the model of Troyer et al. (Troyer, Krukowski, Priebe, & Miller, 1998; Troyer, Krukowski, & Miller, 2002) takes into account antiphase or push-pull inhibition in the afferent inputs of V1 neurons, where stimuli of the reverse contrast of the neuron's receptive field invoke responses of the opposite sign (inhibition). The response of the neuron therefore relies on the balance of excitation and inhibition that the stimulus invokes. Such a mechanism was first proposed by Hubel and Wiesel (1962), and has since been supported by both extracellular (L. A. Palmer & Davis, 1981) and intracellular (Ferster, 1988; Hirsch, Alonso, Reid, & Martinez, 1998) experiments.

The push-pull model has been used to account for contrast-invariant tuning of orientation in V1 spiking activity (Sclar & Freeman, 1982; Skottun et al., 1987). This phenomenon is inconsistent with the simple LN model in which more and more units respond to a non-preferred orientation as the contrast increases, thus broadening the tuning curve. Such an “iceberg effect” (Rose & Blakemore, 1974) in the LN model can be alleviated by including push-pull inhibition in the input, which effectively adjusts the threshold of the neuron to keep the “underwater” part from exposing as the excitatory input pushes the iceberg higher.

Although the push-pull model provides a plausible hypothesis of contrast-invariant tuning in V1, it still does not account for the temporal dynamics of neural response.

### 3.2.3 Spatially organized LN units

Even though the LN model targets single neurons, it can also be a reasonable model for the average response of a small group of neurons such as a cortical column. A region of a cortical area can therefore be modeled by a two-dimensional arrangement of such units. Because of the simplicity and computation efficiency of the LN model, such an abstraction has been used extensively to understand the development of the two-dimensional organization and connectivity in the primary and secondary visual cortex (Miikkulainen et al., 2005; Sirosh & Miikkulainen, 1994; Sit & Miikkulainen, 2006, 2009).

One specific prediction of such models is that the membrane potentials at different locations rise and fall at the same time, regardless of the stimulus contrast. This prediction is not consistent with the VSDI responses in V1 for a Gabor stimulus, where locations further away from the center of activation rises more slowly, producing a travelling wave (Grinvald et al., 1994) (see also Chapter 4).

### 3.2.4 Modeling lateral propagation with the LN model

A common view of the traveling wave of responses is that it results from propagation through slow lateral connections (Grinvald et al., 1994; Sit & Miikkulainen, 2007). If such lateral spread were the only source of the response beyond a critical distance from the center, then beyond this critical distance the responses should be delayed as a linear function of distance. Such delays should be evident because of these connections' relatively slow propagation speed (0.1-0.4 mm/ms; Hirsch & Gilbert, 1991; Murakoshi et al., 1993; Grinvald et al., 1994; Nelson & Katz, 1995; González-Burgos et al., 2000; Telfeian & Connors, 2003). As will be shown in the next chapter, such delays are not observed in the VSDI responses. In fact, as will be shown in Chapter 5, the computational model proposed in this dissertation suggests that slow lateral connections are not required to account for the traveling wave.

## 3.3 Models with temporal integration of inputs

A major problem with models that only combine instantaneous input is that they do not take into account the temporal dynamics of the neuron. A popular approach to model such dynamics is to represent a neuron as a single parallel resistor-capacitor (RC) circuit (Figure 3.2). In such models, previous inputs are accumulated in the capacitor, with some leakage through the resistor, affecting the temporal dynamics of the potential.

### 3.3.1 Leaky integrate-and-fire (LIF) model

In the leaky integrate-and-fire (LIF) model, a neuron is represented by a parallel resistor-capacitor (RC) circuit (Lapicque, 1907; Hill, 1936; Stein, 1965, 1965; Nischwitz & Glünder, 1995; Gabbiani & Koch, 1998; Gerstner & Kistler, 2002; see Burkitt, 2006a, 2006b for review). As can be seen in Figures 2.5 and 3.2, this RC circuit is a simplified version of the circuit in the Hodgkin-Huxley model (Hodgkin & Huxley, 1952) for a short membrane segment. Although the standard leaky integrate-and-fire neuron model cannot be reduced from the Hodgkin-Huxley model directly, it is possible to approximate the Hodgkin-Huxley model by a first-order response kernel expansion in terms of a single variable describing the membrane voltage to a form of the leaky integrate-and-fire neuron model (Kistler, Gerstner, & van Hemmen, 1997).

The voltage  $V(t)$  across the capacitor represents the membrane potential of the unit in the LIF model.

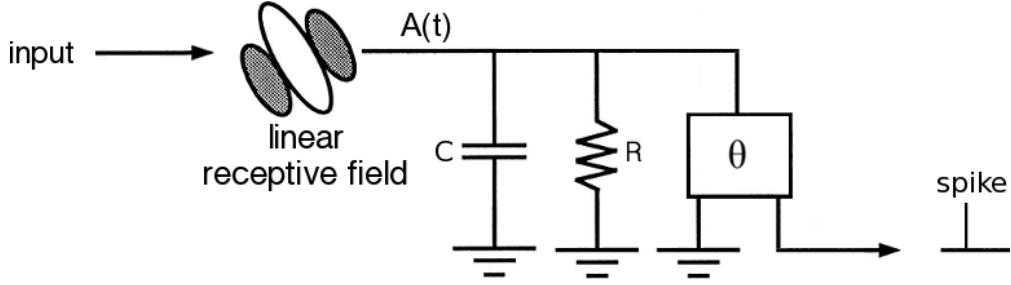

Figure 3.2: **Temporal integration of inputs and spike generation.** The driving current  $A(t)$ , which represents the receptive field summation of the input, charges the capacitor of the circuit. When the voltage across the capacitor is higher than the threshold  $\theta$ , a spike is generated. At the same time, the circuit is shorted to reset the voltage of the capacitor. Past inputs are integrated in the circuit with some leakage through the resistor, thus affecting the temporal dynamics of the potential across the capacitor.

In its simplest form,  $V(t)$  is governed by the equation

$$C \frac{dV}{dt} = A(t) - \frac{V}{R}, \quad (3.2)$$

where  $C$  is the capacitance,  $R$  the resistance, and  $A(t)$  the driving current that represents the receptive field summation as in the LN model. Both  $C$  and  $R$  are constant. The change in potential at a particular time is therefore proportional to the difference between the driving current that charges the capacitor and the leakage current that passes through the resistor. In other words, the membrane potential at any time results from integrating the driving current over time with some leaks. When the membrane potential reaches a threshold, the neuron spikes; hence the name of the model.

When the membrane potential crosses the threshold  $\theta$ , it is reset to the resting potential and integration is inactivated for a brief time  $t_{\text{abs}}$  that models the absolute refractory period of a neuron. For a constant driving current  $A$ , the firing rate  $\eta$  of the unit is therefore limited by  $t_{\text{abs}}$  and the time  $t_\theta$  to reach threshold after the membrane potential is reset, i.e.  $\eta = 1/(t_{\text{abs}} + t_\theta)$ . By integrating equation 3.2,  $t_\theta$  can be found:

$$\theta = AR(1 - \exp(-t_\theta/\tau)) \quad (3.3)$$

$$t_\theta = \tau \ln \frac{AR}{AR - \theta}, \quad (3.4)$$

where  $\tau = RC$ . If  $A$  is very large,  $t_\theta$  will be close to zero and the firing rate of the unit will be saturated ( $\eta = 1/t_{\text{abs}}$ ). Thus, the absolute refractory period prevents the firing rate from being arbitrarily high.

For a local homogeneous population of independent LIF neurons, the mean membrane potential is the average potential over the firing period:

$$\frac{\int_0^{t_\theta} AR(1 - \exp(-t/\tau)) dt + \int_{t_\theta}^{t_\theta + t_{\text{abs}}} 0 dt}{t_\theta + t_{\text{abs}}} \quad (3.5)$$

$$= AR \frac{t_\theta + \tau e^{-t_\theta/\tau} - \tau}{t_\theta + t_{\text{abs}}} \quad (3.6)$$

$$= AR \frac{t_\theta - \tau(1 - e^{-t_\theta/\tau})}{t_\theta + t_{\text{abs}}} \quad (3.7)$$

$$= AR \frac{t_\theta - \tau \frac{\theta}{AR}}{t_\theta + t_{\text{abs}}} \quad (3.8)$$

$$= \tau \frac{AR \ln \frac{AR}{AR-\theta} - \theta}{\tau \ln \frac{AR}{AR-\theta} + t_{\text{abs}}}. \quad (3.9)$$

As  $A$  increases, the numerator approaches zero ( $\lim_{A \rightarrow \infty} AR \ln \frac{AR}{AR-\theta} = \theta$ ); the membrane potential takes less and less time to reach the threshold and in the limit, it becomes an impulse. In other words, a large portion of the period is spent in the reset state rather than building up the potential. The denominator is dominated by  $t_{\text{abs}}$  as  $A$  increases. The mean membrane potential of the population therefore decreases as  $A$  increases. This result predicts that as the contrast of the visual stimulus approaches a level that saturates the response, the average membrane potential actually goes down. As will be shown in the next chapter, such a decrease is not observed in the VSDI responses.

### 3.3.2 Spatially organized leaky integrators

A region of a cortical area can be modeled by a spatially organized network of leaky integrators (Wilson & Cowan, 1972, 1973; Amari, 1977; Abbott & van Vreeswijk, 1993; Ben-Yishai et al., 1995; Somers et al., 1995; Nykamp & Tranchina, 2000), with each unit representing a local population of neurons. The modeled region is usually assumed to be continuous and the units are labeled by their coordinates in the region. This continuous organization allows interaction between two points of the cortex to be modeled in a straightforward way. For a one-dimensional model, the general formulation is

$$C \frac{\partial V(x, t)}{\partial t} = A_{\text{int}}(x, t) + A(x, t) - \frac{V(x, t)}{R}, \quad (3.10)$$

where  $A_{\text{int}}(x, t)$  represents the current at  $x$  due to the interaction from the other units at time  $t$ . The rest of the variables have the same meaning as in the single LIF unit described above.

The interaction current  $A_{\text{int}}(x, t)$  at a given unit depends on the spiking activity of the presynaptic units and the strength of the synaptic connections. In these models, the membrane potential is not reset and the refractory period is ignored. Instead, the potential  $V$  is related to the (population) firing rate by a fixed instantaneous function  $s(V)$ . This function is usually a sigmoidal function or a rectifying function with a threshold. The connection weight  $w$  between any two locations in the model is assumed to be a function of their distance and the profiles of connections are the same for all units. The interaction current is therefore

$$A_{\text{int}}(x, t) = \int w(|x - y|)s(V(y, t)) dy. \quad (3.11)$$

Combining equations 3.10 and 3.11, the formulation of such models becomes a nonlinear integro-differential equation:

$$C \frac{\partial V(x, t)}{\partial t} = \int w(|x - y|)s(V(y, t)) dy + A(x, t) - \frac{V(x, t)}{R}, \quad (3.12)$$

which is referred to as the field equation (Wilson & Cowan, 1973; Amari, 1977).

Although the field equation is complicated, analytical solutions exist for the steady-state for certain types of input and connection weight profiles. In particular, using a weight profile that looks like a Mexican hat (local excitation and global inhibition) within a hypercolumn, stable solutions to the field equation exist such that the orientation tuning of the units is contrast-invariant (Ben-Yishai et al., 1995; Somers et al., 1995; Hansel & Sompolinsky, 1998). On the other hand, the amplitude of the membrane potential in such models simply scales with the input and does not saturate. Also, for inputs containing two peaks in space,

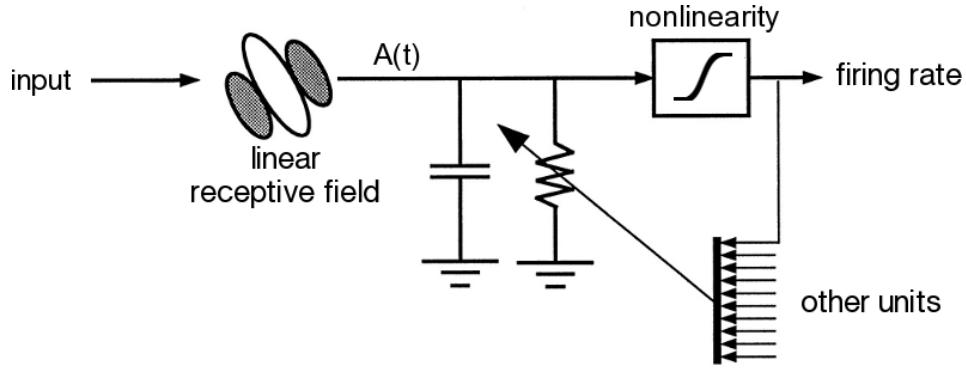

Figure 3.3: **A normalization gain control model.** As in the LIF model, inputs are integrated in the RC circuit. However, the conductance of the circuit is not constant and increases with the sum of activity of other units. Because the voltage across the capacitor is inversely related to the conductance of the resistor, the conductance acts as a divisive (normalizing) factor on  $A(t)$ , thus keeping the response within the dynamic range of the unit. The normalization model has been used to account for many nonlinear properties of the *single unit* firing-rate responses in V1. However, it is unclear how such models can be extended to account for the spatiotemporal dynamics of population responses over a large area. The major contribution of this dissertation is to provide a generalization of the normalization model that can account for these dynamics for a variety of stimuli. Figure adapted from Carandini et al., 1997.

the peaks of the steady-state potential are shifted from the corresponding locations of the input (Carandini & Ringach, 1997). As will be shown in the Chapters 4 and 6, these two properties are inconsistent with the VSDI responses in V1.

### 3.4 Normalization gain control models

The LN and LIF models discussed above accumulate input linearly and then apply a saturating nonlinearity to the sum to generate the response. As a result, there is a fixed and limited range of inputs that elicit graded responses without saturation. This is a problem because dynamic range of natural scenes is usually very large. For example, the ambient luminance ranges from  $10^{-3}$  cd/m<sup>2</sup> in starry night sky to  $10^5$  cd/m<sup>2</sup> under daylight. However, the dynamic range of neural spiking activity is orders of magnitude smaller (0-10<sup>2</sup>). The units in these two models will therefore either have limited resolution for a large-range input, or they will only be sensitive for a certain input range. Models with normalization gain control (NGC) alleviate this problem by scaling, or normalizing, the sum of inputs to a suitable range before passing it through the saturating nonlinearity.

Normalization gain control models (Albrecht & Geisler, 1991; Heeger, 1992; Carandini & Heeger, 1994; Carandini et al., 1997; Mante et al., 2008) are functional models, with several conceptual implementations. Figure 3.3 shows how an RC circuit similar to the LIF model can achieve normalization gain control through a conductance that increases with the activity of a local group of units. Note that the output of the NGC model is a firing rate instead of individual spikes as in the LIF model. Because the voltage across the capacitor is inversely related to the conductance of the resistor, the conductance acts as a divisive (normalizing) factor on the driving current  $A(t)$ . When the activity in the group is large, the conductance will be high, which scales down  $A(t)$  before the nonlinearity to avoid saturation in the firing rate. A proper operating range can thus be maintained.

The NGC model has been used to account for many nonlinear properties of the *single unit* spiking

responses in the LGN and V1, such as saturation (Albrecht & Hamilton, 1982), contrast-invariant tuning (Skottun et al., 1987; Albrecht & Geisler, 1991; Sclar & Freeman, 1982; Albrecht & Geisler, 1991), and phase advance of response at high stimulus contrasts (Carandini et al., 1997). It has also been used to understand the development of the two-dimensional organization and connectivity in the cortex (Bednar, 2002; Miikkulainen et al., 2005). However, it is unclear how such models can be extended to account for the spatiotemporal dynamics of population responses over a large area. The major contribution of this dissertation is to provide a generalization of the NGC model that can account for these dynamics for a variety of stimuli.

### 3.5 Conclusion

Three common families of models of neural processing were reviewed in this chapter. Models that combine inputs instantaneously do not account for the temporal dynamics of the response. With slow lateral interactions among units, such models predict that responses will be delayed in locations further away from the center of activation. This prediction will be tested (and rejected) for the VSDI responses in the next chapter.

In the LIF model, individual units that reset membrane potential for the refractory period will have a decreased average potential as the input becomes stronger. On the other hand, a spatially organized interconnected network consisting of leaky integrators predicts that the response does not saturate. These predictions will both be shown to be inconsistent with the VSDI responses in the next chapter.

The more general NGC model can account for many properties of single unit responses, but it is unclear how such models can be extended to account for the spatiotemporal dynamics of population responses over a large area. A generalization of the NGC model will be provided in this dissertation that can account for these dynamics for a variety of stimuli, after characterizing the properties of the VSDI responses in the next chapter.

# Chapter 4

## Population Responses in the Monkey Primary Visual Cortex

To test the various predictions of the models discussed in the previous chapter, it is necessary to measure and characterize the population responses in the visual cortex accurately. This chapter provides the first quantitative description of the real-time spatiotemporal dynamics of V1 population responses to brief, localized visual stimuli. There are several unexpected properties that are not obvious from single unit responses and are inconsistent with the models reviewed in the previous chapter. A new model that can account for these properties will be introduced and validated in subsequent chapters.

### 4.1 Motivation

To understand visual processing in the brain, it is important to characterize the properties of V1 population responses. However, most studies of V1 have only measured the responses of individual or small groups of neurons; spatiotemporal properties of the whole neural population have not been characterized. In addition, in most of these studies, drifting stimuli with relatively long durations (several seconds) have been used to approximate a steady-state condition. However, natural saccadic inspection of a visual scene typically produces transient stimulation, i.e. 200- to 300-ms fixations separated by rapid eye movements. Furthermore, while it is common to analyze cortical responses by their peaks and latencies (phases) for drifting stimuli, the falling edges of the responses can potentially provide useful information for briefly presented stimuli (Bair, Cavanaugh, Smith, & Movshon, 2002). Thus, to fully understand the properties of V1 responses under natural conditions, it is necessary to use brief stimuli and take the complete time courses of the population responses into account.

### 4.2 Measuring population responses with voltage-sensitive dye imaging (VSDI)

Voltage-sensitive dye imaging (VSDI; Grinvald & Hildesheim, 2004) was used to measure population responses in the superficial layers of macaque V1 over an area of approximately  $1\text{ cm}^2$  that covers the entire region of activity at high spatial and temporal resolution (Figure 2.4; Seidemann, Arieli, Grinvald, & Slovin, 2002; Slovin, Arieli, Hildesheim, & Grinvald, 2002). This section describes the experimental procedures and explains how I analyzed the VSDI signals.

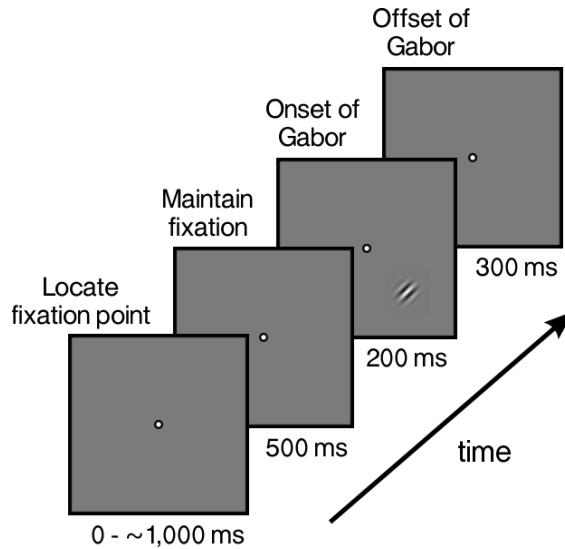

Figure 4.1: **The task performed by the monkey.** Each trial began when the monkey fixated on a small spot of light on a video display. Following an initial fixation (500 ms), a Gabor stimulus was presented at a fixed location for 200 ms; the trial ended 300 ms after the stimulus offset. Throughout the trial, the monkey was required to maintain gaze around the fixation point in order to obtain a reward. This fixation task enables the complete time course of the population responses to be recorded.

#### 4.2.1 Behavioral task and visual stimuli

A macaque monkey was trained to maintain fixation while a small oriented stationary Gabor stimulus was presented on a uniform gray background (Figure 4.1). Each trial began when the monkey fixated on a small spot of light ( $0.1^\circ \times 0.1^\circ$ ) on a video display. Following an initial fixation, the Gabor stimulus was presented for 200 ms at  $2.2^\circ$  eccentricity, with  $\sigma$  of  $0.167^\circ$  and spatial frequency of 2.5 cycles per degree. Throughout the trial, the monkey was required to maintain gaze within a small window ( $< 2^\circ$  full width) around the fixation point in order to obtain a reward. Early fixation breaks invalidated the trials, which were not included in the analysis. Each block of trials contained eight to twelve different contrasts from 0% (blank) to 100% presented pseudorandomly, with an intertrial interval of 6 to 8 seconds. Ten valid trials were run for each condition.

In a separate set of experiments that will be presented in Chapter 5, the width of the Gabor stimulus was either  $0.167^\circ$  or  $1^\circ$  in each trial. The contrast of the stimulus was 100%, and it was presented for 100 ms. The other parameters of the stimulus were the same as the experiment described above. These experiments were designed and run by my collaborator Yuzhi Chen.

#### 4.2.2 Analysis of imaging data

Imaging data were collected at 100 Hz at a resolution of  $512 \times 512$  pixels. The size of each pixel was  $37 \times 37 \mu\text{m}^2$ . The data was preprocessed in four steps. (i) The responses were normalized at each pixel by the average fluorescence at that pixel across all trials and frames. (ii) For each pixel, a linear trend that was estimated based on the response in the 100-ms interval before stimulus onset was removed. (iii) Trials with aberrant VSDI responses (generally less than 1% of the trials) were removed. (iv) The response to the blank condition was subtracted from conditions that included the stimulus.

To remove trials with aberrant VSDI responses, the average time course across all repetitions in a

given condition was subtracted from the response in each trial, and the standard deviation of the residuals was computed at each frame. Trials with residual responses that were greater than three standard deviations were excluded from further analysis. This simple procedure eliminates trials where the animal made excessive movements.

After the preprocessing, the spatial properties of the responses in individual trials were determined. First, the center of the spatial response of each experiment was estimated by fitting a two-dimensional (2D) Gaussian to the average response taken over a time window of 160 to 260 ms after stimulus onset (shaded region in Figure 4.3a) for stimulus contrasts from 25% to 100%. This center was then held fixed, while the average response over the same time window was fitted with a 2D Gaussian to determine the lengths of the major and minor axes and the orientation of the major axis for each trial in each condition of the experiment.

To include more trials at each contrast level in the analysis, a pooled dataset was formed by combining the responses of five experiments on one monkey. Due to the slight difference in the setup of each experiment, the spatial responses were translated and rotated with respect to each other. To align the data, the center and average orientation of the 2D Gaussian fit of each experiment were used to transform the data so that the spatial responses aligned and overlapped in all the experiments. Data from individual experiments are similar to the combined data.

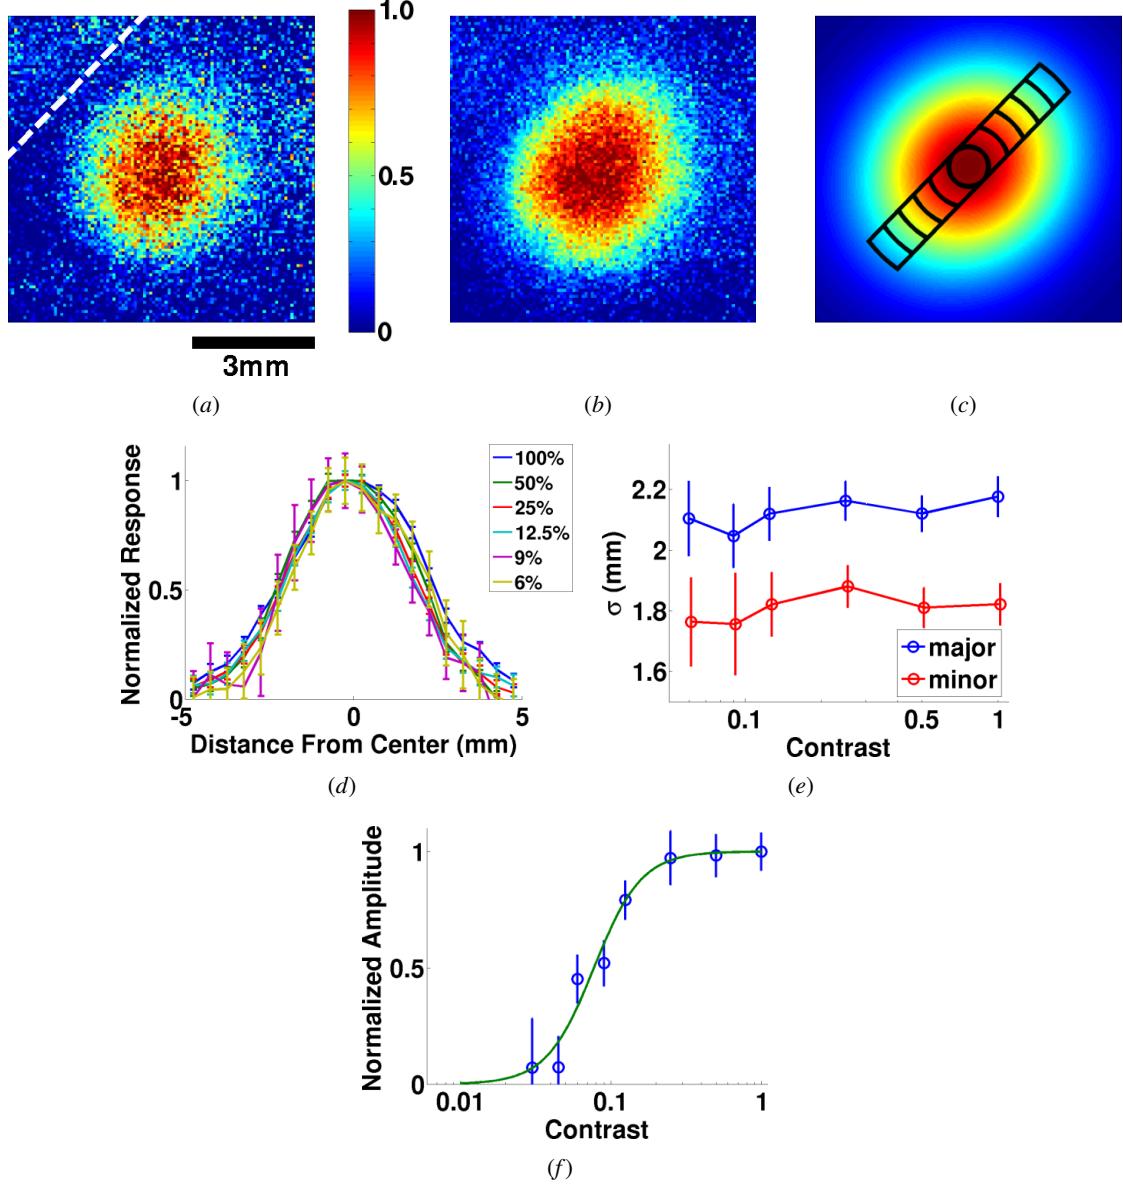

## 4.3 Population responses to a Gabor stimulus in V1

In this section, the spatiotemporal properties of the VSDI responses measured in the experiments will be characterized in detail. Since the VSDI responses in V1 are largely determined by the contrast of the Gabor stimulus, this dissertation focuses on the entire region in V1 that responds to the contrast envelope of the stimulus.

### 4.3.1 Peak responses

The peak responses were taken by averaging the responses over a fixed 100 ms window (160 to 260 ms after stimulus onset; shaded region in Figure 4.3a). The spatial distributions of the peak responses at two contrasts are shown in Figures 4.2a and b. The spatial responses are well fitted by two-dimensional Gaussians (Figure 4.2c). The Gaussians are elongated because of the anisotropic mapping of visual space in V1 (Van Essen et al., 1984; Blasdel & Campbell, 2001; Yang et al., 2007). Importantly, the extents of the spatial responses are similar at low and high contrasts (Figure 4.2d). In fact, as was shown in a previous VSDI study (Y. Chen et al., 2006, 2008), the widths of the Gaussian fits are not significantly different across different contrasts (one-way ANOVA,  $p > 0.1$  for both major and minor axes; Figure 4.2e). The widths of the spatial responses are hence largely contrast-invariant.

The average width ( $\sigma$ ) of the major axis of the fit is 2.1 mm and the minor axis is 1.8 mm wide. The width of the stimulus is  $0.167^\circ$  and the cortical magnification factor that was measured in the same recording chamber is  $\sim 3$  mm/deg at the eccentricity of the stimulus (C. R. Palmer, Chen, & Seidemann, 2008). The width of the stimulus thus maps to 0.5 mm on the cortex through the cortical magnification factor alone. The spatial response is hence much larger than the direct mapping of the stimulus to the cortical space. This spread is not significantly affected by the small variability in the monkey's eye position (Y. Chen et al., 2006). Instead, the widening is mainly due to the convergence and divergence of afferents into the receptive fields of V1 neurons, which determine the image of a point in the cortex (cortical point image; Hubel & Wiesel, 1974; Dow, Snyder, Vautin, & Bauer, 1981; Van Essen et al., 1984). In addition, some of

**Figure 4.2: Peak responses to a Gabor stimulus.** The responses were averaged across all experiments and over a fixed 100 ms time window (shaded region in Figure 4.3a). (a,b) Normalized peak responses to the stimulus at 6% (a) and 100% (b) contrasts in space. As expected from the anisotropy in the map of visual space in V1 (Van Essen et al., 1984; Blasdel & Campbell, 2001; Yang et al., 2007), the spatial profile is elongated along the axis parallel to V1/V2 border (white dashed line in (a)). (c) 2D Gaussian fit of the response in (b). The outlined regions represent the intersection between a 1.0 mm strip along the major axis and six concentric circular annuli of width 0.5 mm. The central annulus is a disk with 0.5 mm radius. The responses of the pixels in the groups that are equidistant from the center are averaged for further analysis in Figures 4.3 to 4.7. (d) Normalized peak responses along the major axis at different stimulus contrasts. Error bars represent the standard errors across individual trials in all the figures. (e) The average widths of the Gaussian fits at different contrasts. The mean for the major axis is 2.1 mm and 1.8 mm for the minor axis. (f) Contrast response function at the center. The solid curve is the Naka-Rushton equation fit to the data (open circles,  $r^2 = 0.98$ ). The spatial profiles of the peak responses are therefore largely contrast-invariant, even though the responses saturate at high contrast, as was shown previously (Y. Chen et al., 2006, 2008).

this widening could reflect significant lateral spread of activity through lateral connections in V1 (Gilbert & Wiesel, 1979; Rockland & Lund, 1983; Martin & Whitteridge, 1984) and significant contribution from feedback connections (Angelucci, Levitt, & Lund, 2002; Angelucci, Levitt, Walton, et al., 2002).

Figure 4.2f shows the average peak response over a circular region of 0.5 mm radius at the center of the response profile (central disk outlined in Figure 4.2c) as a function of stimulus contrast. Similarly to single units, the responses follow a sigmoidal function on a log contrast axis; the solid curve is a Naka-Rushton function ( $C^n / (C_{50}^n + C^n)$ ; Naka & Rushton, 1966) fitted to the data ( $r^2 = 0.98$ ).

The peak response is a nonlinear function of contrast and saturates at about 25%. This result is inconsistent with models in which the response scales with input, such as the push-pull inhibition models (Troyer et al., 1998, 2002; Section 3.2.2) and some of the spatially organized leaky integrators (Ben-Yishai et al., 1995; Somers et al., 1995; Hansel & Sompolinsky, 1998; Section 3.3.2). After saturation, the VSDI response does not decrease as contrast increases, which is inconsistent with the LIF models (Section 3.3.1).

### 4.3.2 Overview of the temporal response properties at different locations

To analyze the response properties at different locations in V1, the imaged pixels were divided into small bins according to their distances from the center of activity. The image was first divided into concentric annular regions 0.5 mm wide, centered at the peak of the spatial response, with the central region being a disk with a 0.5 mm radius. The pixels in the central region had an average distance of 0.25 mm from the center, and this distance increased by 0.5 mm in each annulus. Due to the anisotropic response profile, pixels that are at the same distance from the center can have different response amplitudes and potentially different temporal dynamics. Therefore, it is inappropriate to bin pixels according to distances alone. Instead, only the pixels within a 1 mm wide strip along the major axis of the fitted Gaussian profile were considered. Within this strip the relationship between distance and amplitude was nearly constant. The temporal responses of the pixels within each annulus that were also inside of the strip were averaged to produce a single time course for the corresponding distance. Figure 4.2c shows the bins up to an average distance of 2.75 mm. Responses at locations further away were not analyzed because they were weak and noisy, especially at lower contrasts.

Figure 4.3a shows the average time courses of the responses at the center bin for different stimulus contrasts. To characterize these time courses quantitatively, they were first divided into two parts. The first part, defined as the rising edge, was the response in the first 210 ms after the stimulus onset. The rest of the time course was defined as the falling edge. Each individual edge from each trial was smoothed by a five-frame moving average, normalized, and then fitted separately with a logistic function  $1 / (1 + e^{\lambda(t-t_{50})})$  (e.g., Figure 4.3b). The parameter  $t_{50}$  is the time that the response reaches half of its peak, and  $\lambda$  describes the slope of the response. For example, a  $\lambda$  of 0.05 means that the response takes about 44 ms after  $t_{50}$  to reach 90% of the peak. The same fitting procedure was applied independently at the different locations shown in Figure 4.2c for each stimulus contrast. The latency of the rising edge ( $t_{10}$ ) was defined as the time after stimulus onset for the fitted response to reach 10% of its amplitude, where the change in slope is high. Similarly, the latency of a falling edge is defined as the time it takes for the response to decrease by 10% from the peak after stimulus offset.

Figure 4.3c shows the latencies of the rising and falling edges as a function of contrast in the center bin. As observed in single neuron studies (Dean & Tolhurst, 1986; Carandini & Heeger, 1994; Albrecht, 1995) and Figure 4.3b, the latency of the rising edge decreases as stimulus contrast increases (one-way ANOVA,  $p < 0.01$ ). On the other hand, there is no significant difference in the falling edge latencies for different contrasts (one-way ANOVA,  $p > 0.15$ ). Asymmetric properties between rising and falling edges

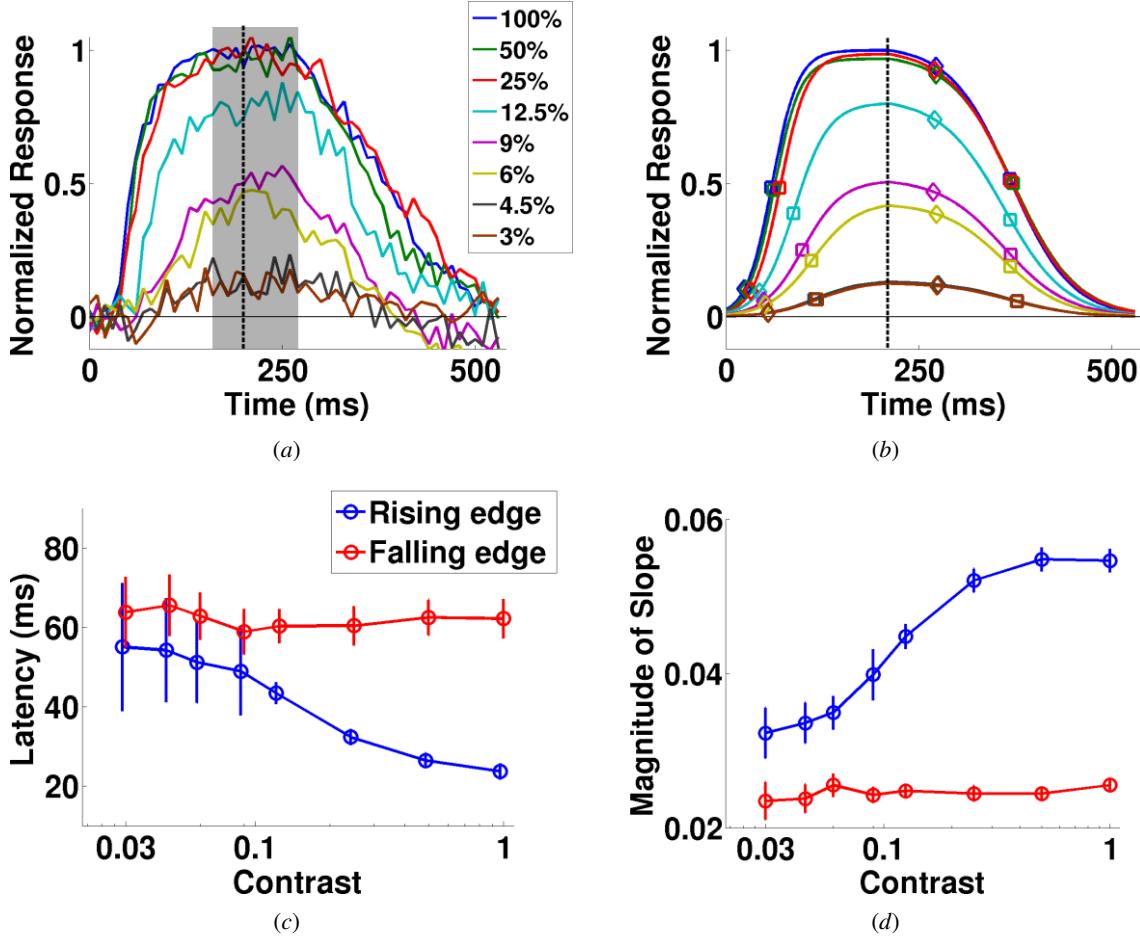

Figure 4.3: **Temporal responses to different stimulus contrasts at the center.** (a) Time courses of the normalized responses in the center disk of Figure 4.2c. The stimulus was presented at time 0 and disappeared after 200 ms (dotted line). Average responses in the shaded area were used to compute the spatial profiles and contrast response function in Figure 4.2. (b) Logistic fits of the time courses in (a). The time courses were divided into two parts by the dotted line at 210 ms. Each part was fitted separately by a logistic function. Diamond and square symbols on each part indicate the latencies and times to half peak, respectively. Latencies (c) and slopes (d) of the rising and falling edges of the fitted responses as a function of contrast. While the shape of the rising edge depends on stimulus contrast, that of the falling edge does not. Such asymmetry is a new observation and hence provides new constraints on models of V1.

are also observed in their slopes (Figure 4.3d). The slope of the rising edge becomes steeper as contrast increases (one-way ANOVA,  $p < 0.01$ ), while the falling edge slope remains similar (one-way ANOVA,  $p > 0.15$ ). Such asymmetry is observed in all locations, as will be demonstrated next.

The space-time color plots in Figure 4.4 summarize in a compact form all of the temporal responses as a function of stimulus contrast and position. The normalized fitted responses for each contrast are shown as separate subplots. Within each subplot the time course of the response at each of the six location bins from Figure 4.2c is indicated by a horizontal row, progressing from the center location at the top to the most peripheral location at the bottom. For example, the upper horizontal row in the space-time plot for 100% contrast corresponds to the dark blue curve in Figure 4.3b. Several qualitative observations can be made from these maps, which will be quantified in Sections 4.3.3 and 4.3.4. For each contrast, (1) the response latencies at different locations are approximately equal, as can be seen by the vertically aligned

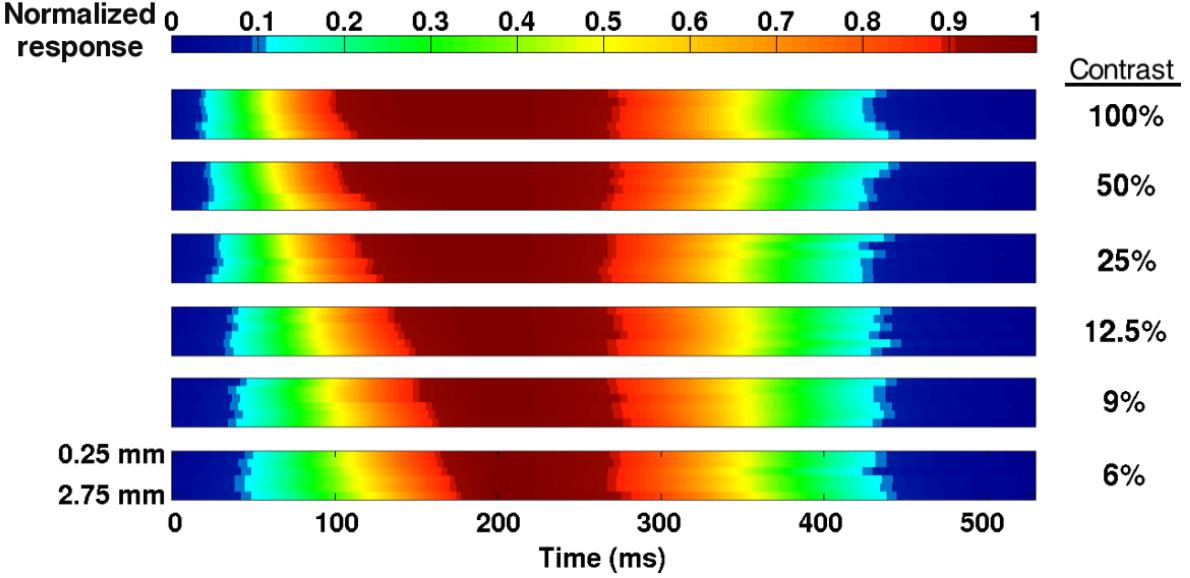

Figure 4.4: **Spatiotemporal responses to different stimulus contrasts.** Logistic fits of the normalized time courses at different locations for each stimulus contrast. Each horizontal row within the space-time plot for a given contrast shows the fitted time course at one location, from the center (top row) to the outmost region (bottom row). There is a systematic change in slope and latency of the rising edges, whereas the falling edges are similar for different contrasts and locations. This rich spatiotemporal response dynamics place strong constraints on models of V1.

transitions from blue to cyan in each map, and (2) the response rises at a slower rate as distance from the center increases, as can be seen by the tilt of the transition between colors as the normalized amplitude increases. In addition, for each location, as contrast increases (3) response latency decreases, and (4) the response rises at a faster rate. Finally, (5) after stimulus offset, the falling edges are similar for all locations and contrasts. As will be shown in the next section, this rich spatiotemporal response dynamics place strong constraints on models of V1.

### 4.3.3 Properties of the rising edge

The above observations can be demonstrated quantitatively using the logistic fits obtained from individual trials. Figure 4.5a plots the rising edge latency ( $t_{10}$ ) as a function of distance from the center bin for each stimulus contrast. There was no significant difference in the latencies at different locations (one-way ANOVA,  $p > 0.1$  for all contrasts). On the other hand, as observed at the center bin, latency of the rising edge decreased as stimulus contrast increased at all locations (one-way ANOVA,  $p < 0.01$  for all locations). These quantitative results confirm qualitative observations (1) and (3).

Figure 4.5b plots the same latency data in Figure 4.5a, but as a function of the peak response. For the same response amplitude, the latency can be different at different stimulus contrasts. For example, responses to a low-contrast stimulus at the center have much longer latency than the response 2.75 mm from the center for a high contrast stimulus even though the response amplitudes are the same. This result demonstrates that the dynamics of the response at a given location in V1 do not depend solely on the local response amplitude, but rather on the response amplitudes over a larger region.

The rate  $\lambda$  at which the response rises depends on both stimulus contrast and on cortical location (Figure 4.5c). For a particular contrast, the slopes at different locations are significantly different (one-way

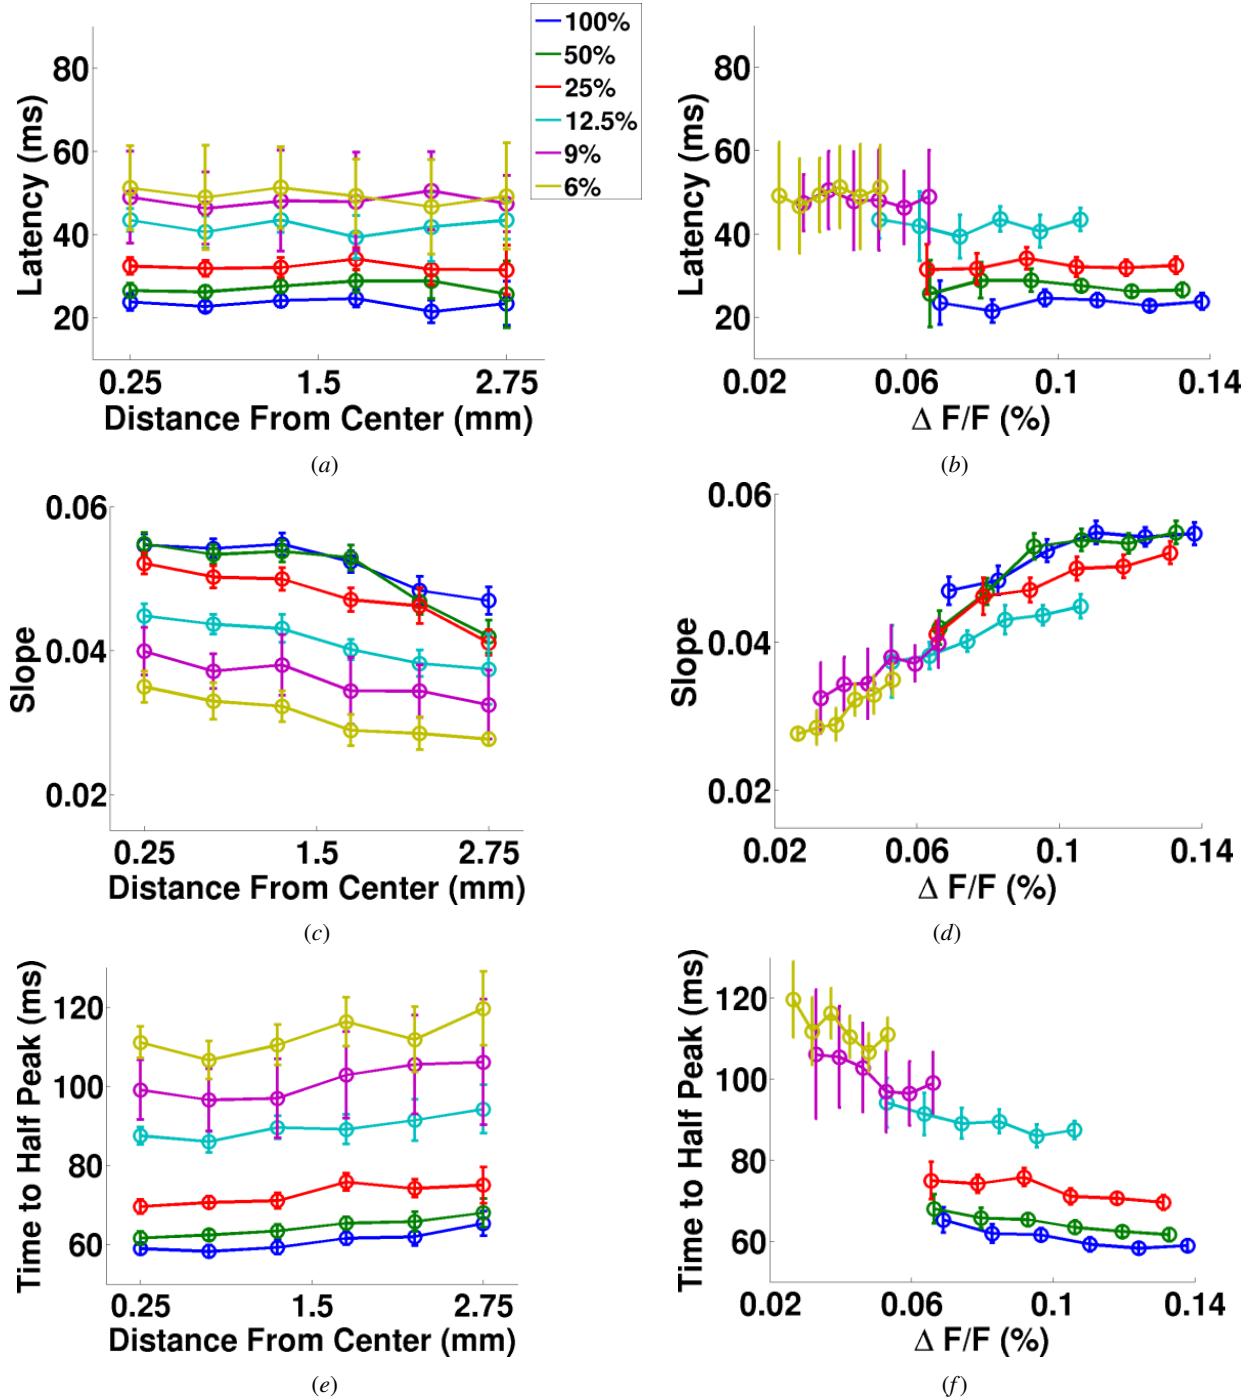

Figure 4.5: **Temporal properties of the rising edge.** Time shown is relative to stimulus onset. (a) Latencies of the responses at different cortical distances from the center. There was no significant difference in the latencies at different locations (one-way ANOVA,  $p > 0.1$  for all contrasts) while the latency of the rising edge decreased as stimulus contrast increased at all locations (one-way ANOVA,  $p < 0.01$  for all locations). (b) The same data as in (a), but plotted as a function of the peak response. Slopes of the responses at different locations (c) and peak responses (d). Time to half of the peak response as a function of location (e) and peak response (f). Combining these results, for a particular contrast, the responses at different locations started to rise at about the same time, but the slopes were shallower at locations that were further away from the center, increasing the times to half peak at these locations (one-way ANOVA,  $p < 0.01$  for all contrasts).

ANOVA,  $p < 0.01$  for all contrasts). The responses at locations that were further away from the center increased more slowly, confirming observation (2). In addition, at a fixed location, the slope of the rising edge increased with contrast (one-way ANOVA,  $p < 0.01$  for all locations), quantifying observation (4). Furthermore, the slope also increased with peak response with a correlation coefficient of 0.94 (Figure 4.5d).

To summarize, combining the first four observations, for a particular contrast, the responses at different locations started to rise at about the same time, but the slopes were shallower at locations that were further away from the center. Lowering the stimulus contrast increased the latencies of the rising edge and decreased their slopes. The time courses of the responses are therefore different at different locations. This result is inconsistent with the LN models that only consider the instantaneous inputs (Sections 3.2.1 and 3.2.3), which predict that the response time courses is the same everywhere.

### Traveling wave of activity and lateral propagation

Due to the decreasing slope as a function of location in the rising edge, the time to half of the peak response ( $t_{50}$ ) increased at locations peripheral to the center of activity. If it was employed as a measure of latency, a wave of activity would appear to be originating from the center (Figure 4.4). The average difference of the time to half peak between locations 0.25 mm and 2.75 mm away from the center was 6.2 ms. This difference corresponds to a propagation speed of 0.4 mm/ms, which is at the higher end of the speed of propagation through lateral connections (0.1-0.4 mm/ms; Hirsch & Gilbert, 1991; Murakoshi et al., 1993; Grinvald et al., 1994; Nelson & Katz, 1995; González-Burgos et al., 2000; Telfeian & Connors, 2003).

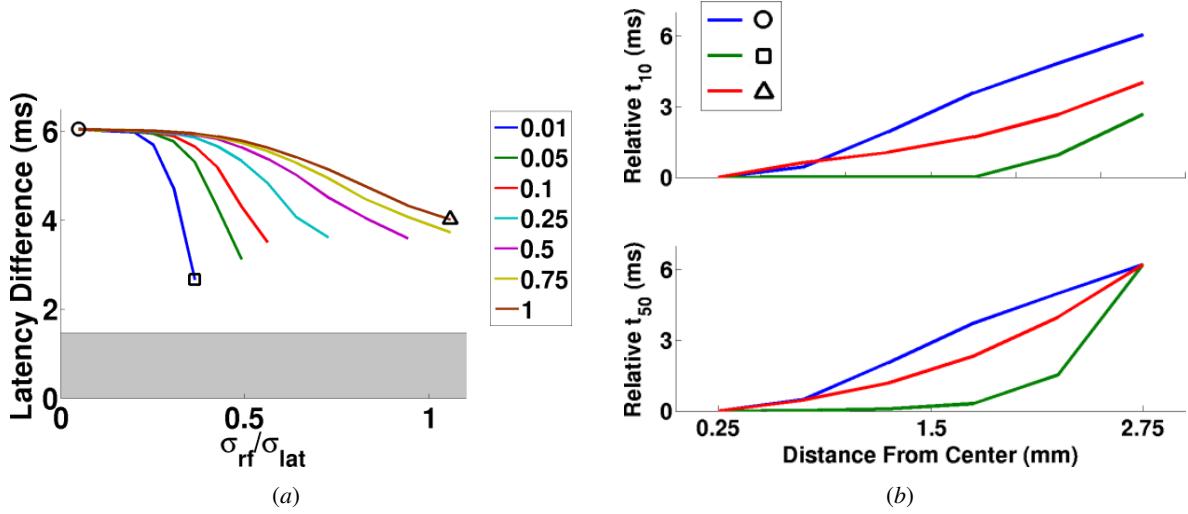

As discussed in Section 3.2.4, if the difference in  $t_{50}$  is solely due to the slow lateral spread, then beyond a certain critical distance the response latency should increase linearly as a function of distance from the center. However, there was no significant difference in the rising edge latency of the VSDI responses for a wide range of distances (Figure 3a). In fact, for 50% and 100% contrast stimuli, rising edge latencies remained the same up to a distance of 3.25 mm (within which a reasonably good fit to the data could be obtained; data not shown).

To investigate how the latencies are affected by lateral propagation in the proximity of the center, a linear model was simulated. The stimulus-driven signal in each model unit was assumed to have the same sigmoidal time course  $A(t)$ , with amplitude  $c(x)$  proportional to the local contrast in the unit's receptive field. These stimulus-driven signals were propagated through lateral connections at a constant speed, which was implemented as a spatiotemporal kernel  $G_l(x, t)$ :

$$G_l(x, t) = \begin{cases} G(x) & \text{if } t = \frac{|x-c|}{v} \\ 0 & \text{otherwise,} \end{cases} \quad (4.1)$$

where  $v$  is the conduction speed,  $c$  is the center of the kernel, and  $G(x)$  is the weighting function of lateral connections. The membrane potential of the unit were the sum of stimulus-driven signals and the incoming lateral signals multiplied by a scaling factor  $w$ :  $c(x)A(t) + w(c(x)A(t)) \otimes G_l(x, t)$ , where  $\otimes$  denotes convolution.

In such a model, the overall strength, extent, and conduction speed of the lateral connections all contribute to the time course of the membrane potential. In the simulation, the spatial strength of the lateral connection  $G(x)$  and the receptive field envelope were assumed to follow a Gaussian profile. The widths of the lateral connections  $\sigma_{\text{lat}}$  and the receptive field  $\sigma_{\text{rf}}$  were therefore constrained by the equation:  $\sigma^2 = \sqrt{\sigma_{\text{stim}}^2 + \sigma_{\text{rf}}^2 + \sigma_{\text{lat}}^2}$ , where  $\sigma = 2.1$  mm is the width of the response profile and  $\sigma_{\text{stim}} = 0.5$  mm is the width of the stimulus used in the experiment. For each scaling factor  $w$  and for each plausible pair of values of  $\sigma_{\text{rf}}$

**Figure 4.6: Effects of lateral propagation on the latency of the rising edge.** (a) The difference in latencies between the locations that were 0.25 mm and 2.75 mm away from the center is plotted as a function of the ratio between the widths of the receptive field and lateral connections for different values of the lateral weight scaling factor  $w$ . Each curve is plotted for the range where a fit to the time to half peak was possible. Shaded region shows the 95% confidence interval (truncated at 0) between the latencies at the two locations in the VSDI responses. (b) The increase in latency (top) and time to half peak (bottom) as a function of distance from the center for the three example points indicated by different symbols in (a). These results show that in order to account for the traveling wave of activity with slow lateral connections, the latency of the rising edges has to be different at different locations, which is inconsistent with the VSDI responses.

and  $\sigma_{lat}$ , the conduction speed  $v$  of the lateral connections was fitted such that the times to half of the peak response at distances 0.25 mm and 2.75 mm differed by 6.2 ms. The latencies ( $t_{10}$ ) at these two locations were then determined from the fitted responses.

Figure 4.6a plots the latency difference as a function of the ratio between  $\sigma_{rf}$  and  $\sigma_{lat}$  for different weights  $w$  over the range where a fit was possible. The difference in latencies is substantial. As the ratio between  $\sigma_{rf}$  and  $\sigma_{lat}$  increased, the fitted conduction speed decreased to compensate for the wider feedforward receptive field. At the end of each curve in Figure 4.6a, the speed was less than 0.01 mm/ms, which is an order of magnitude slower than the speed observed in lateral connections and may not be biologically plausible. For the values of the weight  $w$  that were tested, the predicted differences were larger than the 95% confidence interval of the latency difference in the VSDI responses. This result suggests that linear summation of the delayed signals from lateral connections alone cannot account for the properties of the VSDI responses consistently. Figure 4.6b plots how the latency and time to half peak increase as a function of distance from the center for the two extreme points with  $w = 1$  in Figure 4.6a (circle and triangle symbols) and the rightmost point for  $w = 0.01$  (square symbol). Changing the shape of the stimulus-driven response did not affect these results, as long as it remained sigmoid.

Models with slow propagation of activity therefore do not satisfy with all the anatomical and physiological constraints. However, as will be discussed in the next chapter, such differences in time to half of the peak and other properties can be explained by the population gain control model proposed in this dissertation.

#### 4.3.4 Properties of the falling edge

The dynamics of the falling edge of the responses were markedly different from those of the rising edge. As shown in Figure 4.7, both latency and slope were independent of contrast and location (two-way ANOVA,  $p > 0.15$  across contrasts and locations for both latency and slope). The responses at all locations therefore fell approximately all at once and at the same rate, regardless of the stimulus contrast and response amplitude, supporting observation (5).

The latency of the falling edge ( $t_{10} = 65$  ms) was slightly larger than that of the rising edge at low stimulus contrasts. As contrast increased, the rising edge accelerated, resulting in a shorter latency and steeper slope, while the properties of the falling edge remained the same. The average slope for the falling edge ( $\lambda = 0.026$ ) was shallower than any slope of the rising edge. Such asymmetry in the temporal properties of the rising and falling edges can be explained by the population gain control model presented in the next chapter.

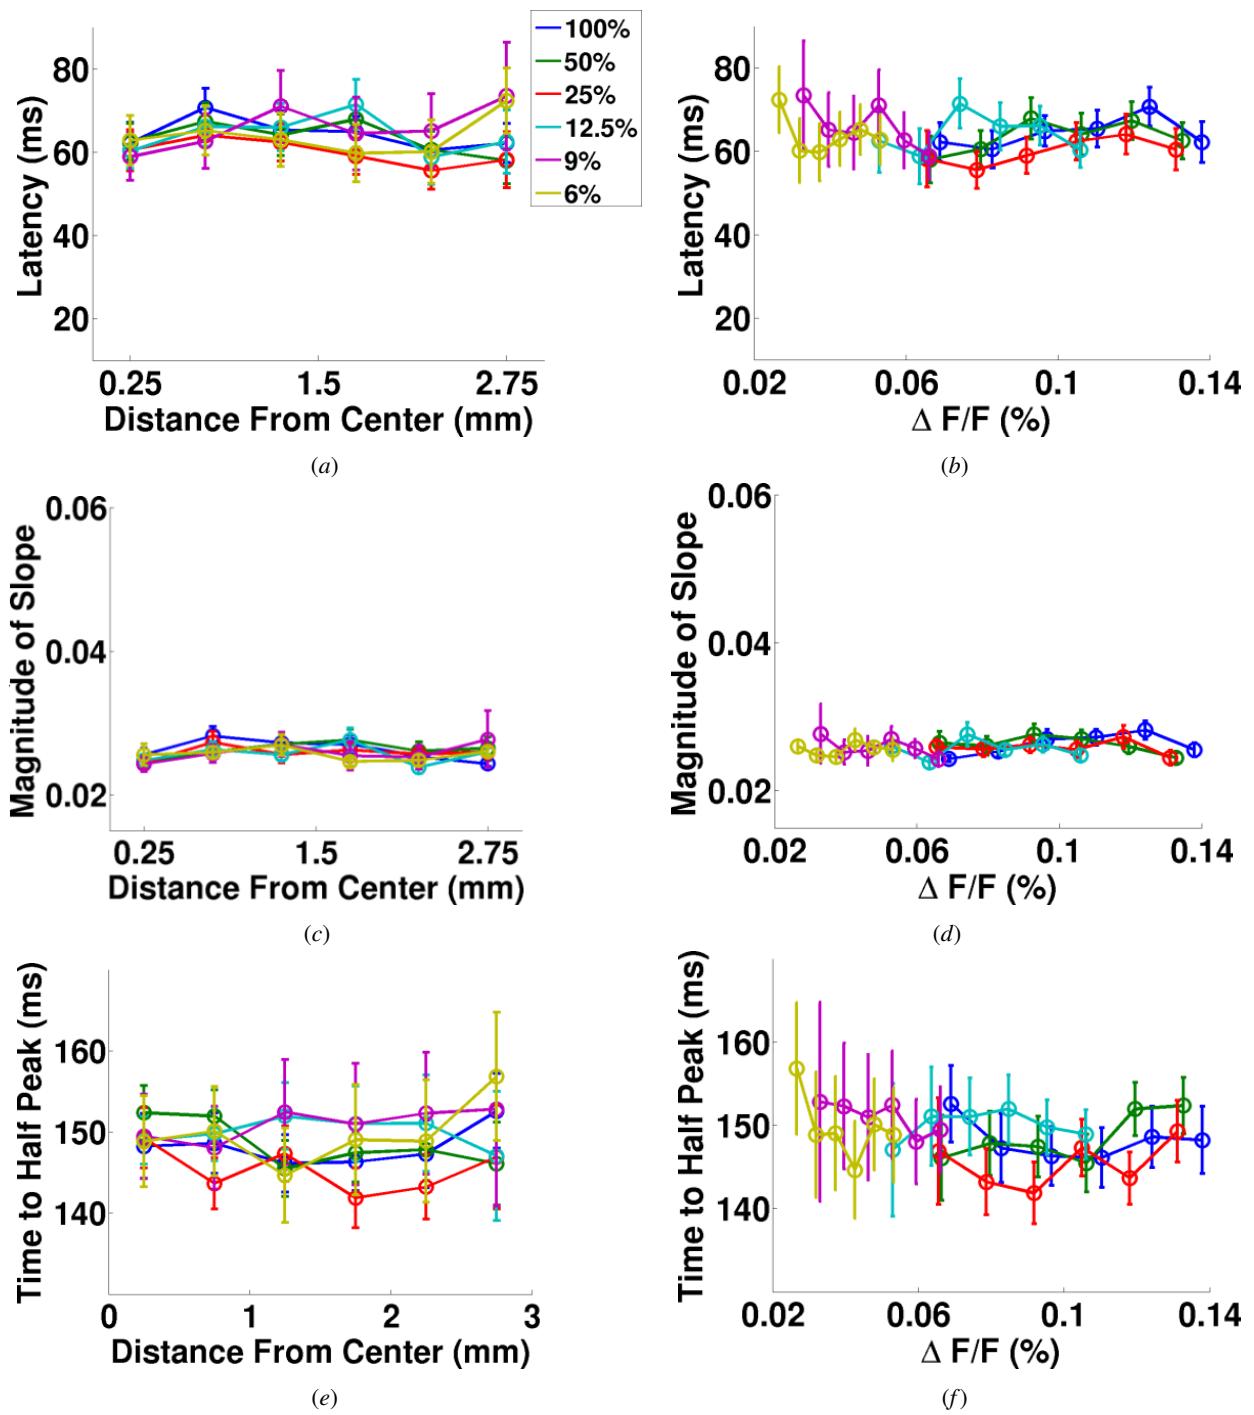

### 4.4 Discussion

Because VSDI measures changes in membrane potentials in a small volume of V1, it is unclear how the VSDI signals relate to the population responses at the level of spiking activity: For instance, they may have different spatiotemporal dynamics. A recent quantitative comparison of VSDI and extracellular microelectrode recordings in V1 of fixating monkeys showed that the relationship between the normalized VSDI responses and spiking activities of small neural populations is nonlinear and can be approximated by a power function (C. R. Palmer et al., 2008). Because a power function of a Gaussian is also a Gaussian but of a different width, and because the spatial profile of the VSDI responses to a small Gabor stimulus is a Gaussian, the spatial profile of the population spiking activities may also be independent of contrast for such stimuli. Further experimental investigations are required to address this and other similar questions concerning the relationship between VSDI signals and spiking activity of a neural population.

Functionally, the power function implements a soft threshold for spiking activity: The normalized VSDI response has to be large enough for the spiking activity to be noticeable. In fact, C. R. Palmer et al. (2008) observed no significant spiking activity in V1 when the normalized VSDI response was below 0.3. Such a threshold can explain some of the discrepancies between the behaviors of single unit and VSDI responses. For example, while the falling edge latency is larger than the rising edge for all contrasts in the VSDI response, the reverse relationship is observed in the firing rates of single units (Bair et al., 2002). The apparent discrepancy is consistent with the fact that the VSDI measures subthreshold membrane potentials (Grinvald et al., 1994). Because of spike threshold, the onset of spiking activity will lag behind the rise in the VSDI response. On the other hand, for the falling edge the drop in spiking activity will coincide with the drop in the VSDI response (as long as membrane potential is above threshold). Thus, for spikes it is quite possible for the onset latency to be greater than the offset latency.

### 4.5 Conclusion

To understand the processing of arbitrary visual stimuli in the cortex, it is important to characterize the properties of V1 population responses. This chapter provides the first quantitative description of the real-time spatiotemporal dynamics of V1 population responses to brief, localized visual stimuli. The population

**Figure 4.7: Temporal properties of the falling edge.** Time is relative to stimulus offset. (a,b) Latencies of the responses as a function of location (a) and peak response (b). (c,d) Absolute value of the slope as a function of location (c) and peak response (d). (e,f) Time to half of the peak response as a function of location (e) and peak response (f). The latencies and slopes were independent of contrast and location (two-way ANOVA,  $p > 0.15$ ).

responses exhibit systematic and unexpected nonlinear properties that are not obvious from single unit responses. First, the spatial profile of the response is constant and independent of stimulus contrast. Second, responses start to rise at all locations simultaneously, but rise at a faster rate at the center of activity than at peripheral locations. Third, both the latency and the steepness of the rising edge of the response depend on stimulus contrast. Finally, after stimulus offset, the responses at all locations fall simultaneously and at the same rate, regardless of stimulus contrast. These results illustrate that unexpected properties can emerge at the level of neural population responses (Seidemann, Chen, & Geisler, 2009). In general, it will be difficult or even impossible to predict the population responses based on a small sample of single-unit measurements in many cases. These unexpected properties demonstrate that it is important to characterize population responses quantitatively in both space and time.

The properties of the VSDI responses, such as response saturation and contrast-dependent slope of the rising edge, are inconsistent with the LN and LIF models for single neurons and spatially organized networks. On the other hand, the NGC models have been shown to account for such properties in single neurons (Albrecht & Geisler, 1991; Heeger, 1992; Carandini & Heeger, 1994; Carandini et al., 1997; Mante et al., 2008). Thus, normalization models are more promising than the other families of models. However, an important question is whether normalization models can account for the other properties observed in the VSDI data, especially the changes in the rising edge at different locations and the invariance of the slope and latency of the falling edge. In the next chapter, a more general form of normalization model called population gain control (PGC) model that can account for all the spatiotemporal properties of the VSDI responses will be presented.

# Chapter 5

## Population Gain Control Model

Normalization gain control models have been used to account for many nonlinear properties of single unit responses in the LGN and V1 (Albrecht & Geisler, 1991; Heeger, 1992; Carandini et al., 1997; Mante et al., 2008). In particular, this family of models can explain response saturation (Albrecht & Hamilton, 1982), contrast-invariant tuning (Skottun et al., 1987; Albrecht & Geisler, 1991; Sclar & Freeman, 1982), and phase advance of response at high stimulus contrasts (Carandini et al., 1997). As shown in the previous chapter, these properties are also observed in the V1 population responses. Thus, normalization models are more promising than other families of models. However, an important question is whether normalization models can account for the other properties observed in the VSDI data, such as the changes in the rising edge at different locations and the invariance of the slope and latency of the falling edge. In this chapter, a more general form of normalization model called population gain control model (Sit, Chen, Geisler, Seidemann, & Miikkulainen, 2008) is defined. This model can account for most of the spatiotemporal properties of the VSDI responses, suggesting that population gain control is a general mechanism of visual processing.

### 5.1 Population gain control (PGC) model

The population gain control (PGC) model is a generalization of the normalization models (Albrecht & Geisler, 1991; Heeger, 1992; Carandini et al., 1997; Mante et al., 2008). In contrast to traditional gain control models, which apply to the temporal dynamics of a single neuron, the PGC model aims at explaining the responses of a large neural population in both time and space.

In the model, the early visual pathway is represented by a network consisting of an input sheet and two stages (Figure 5.1a). The input sheet represents the visual stimulus and does not perform any processing. The first stage in the model represents the nonlinear processing that occurs in the retina, LGN, and layer 4 in V1. While it would be more realistic to model each of these areas individually, there is not enough experimental data at the population level to provide sufficient constraints to do so. The second stage models the superficial layers in V1 from which the VSDI signals are measured. Within each stage, the units are identical and implement the filtering and normalization circuit illustrated in Figure 5.1b.

To simplify the discussion and simulation, each of these sheets are represented by a one-dimensional array, which represents the collapsed data along the major axis ( $x$ -axis) of the VSDI response profile (the black rectangular region in Figure 4.2c). Each sheet thus contains an array of units indexed by  $x$ , where each unit represents the average activity of the small neural population within a pixel in the VSDI image. Extension to two dimensions is straightforward mathematically and results in similar response properties.

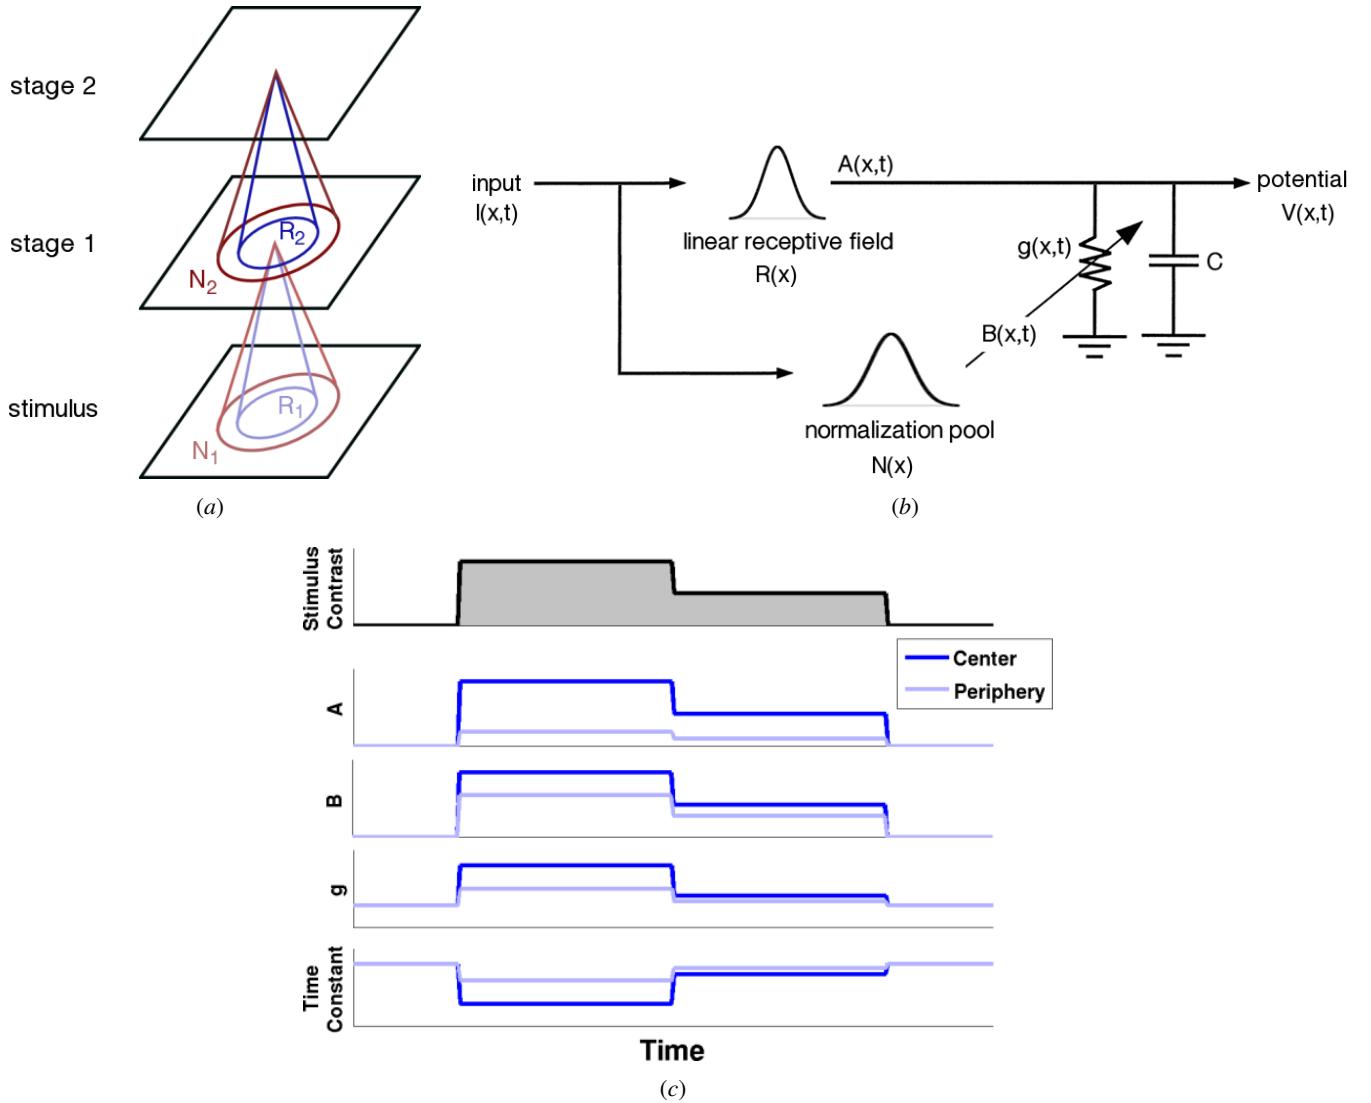

Figure 5.1: **A canonical model of visual processing.** (a) A feedforward gain control model for the early visual pathway. The model consists of an input sheet and two stages. Each sheet is modeled by a spatially organized array of units with the same set of parameters. The input sheet represents the visual stimulus only and does not employ the model in (b). The processing in the first stage represents the nonlinearity in the retina, LGN, and layer 4 of V1, whose spiking responses are fed into the second stage as input. The second stage represents the superficial layers in V1 from which the VSDI signals are measured. The blue and red projections illustrate the receptive fields  $R(x)$  and normalization pools  $N(x)$ , respectively, for two example units in the first (light colors) and second (dark colors) stages of the model. (b) The processing in a model unit. Each unit computes two weighted sums:  $A(x,t)$  from the receptive field, and  $B(x,t)$  from normalization pool.  $A(x,t)$  is the driving current of the parallel resistor-capacitor (RC) circuit that represents the processing at each pixel of VSDI imaging. The conductance  $g(x,t)$  of the resistor is controlled by the normalization activity  $B(x,t)$  and is inversely related to the gain of the circuit, i.e. it has a divisive effect on the sum  $A(x,t)$ . It also affects the dynamics of the response. The voltage across the capacitor is the unit's response. (Figure modified from Carandini et al., 1997.) (c) Example time courses of the model's components at the center and periphery of a hypothetical stimulus.

### 5.1.1 Transforming visual stimuli to model input

Since the VSDI signal in V1 is largely determined by the contrast of the Gabor stimulus rather than its specific orientation and phase, a stimulus is represented by its spatial contrast envelope in the model. In particular, the stationary Gabor stimulus used in the VSDI experiment is represented by a Gaussian. This Gaussian is mapped onto the input sheet through the cortical magnification factor, which is a scaling factor that converts distance in visual space onto the cortex. For simplicity, the cortical magnification factor is assumed to be constant in the modeled region. Note that the input is represented in cortical coordinates rather than retinal coordinates. Since the retinotopic mapping of V1 is fixed, representing stimuli in cortical coordinates directly simplifies the model by carrying out this spatial transformation implicitly and does not affect the results.

To study how normalization affects the spatiotemporal dynamics of the response, there is no temporal filtering in the input sheet except for a fixed delay  $d$ . In other words, the activity  $V_{\text{in}}(x, t)$  of this sheet is simply a delayed version of the stimulus. The amplitude of activity is also assumed to be directly proportional to stimulus contrast. More precisely, the stationary Gabor stimulus

$$h(u, t) = q(t) \exp\left(-\frac{u^2}{2\sigma_u^2}\right) \cos(2\pi f u + p) \quad (5.1)$$

at visual coordinates  $u$  with contrast  $q(t)$  is represented by the following Gaussian in the input sheet:

$$V_{\text{in}}(x, t) = q(t - d) \exp\left(-\frac{x^2}{2\sigma_x^2}\right), \quad (5.2)$$

where  $d$  is the time delay and the visual space coordinates  $u$  are transformed into the input sheet position  $x$  through the cortical magnification factor  $m$  by the relationship  $u = mx$ .

### 5.1.2 Processing in the model units

The units at each stage of the model are modeled by a resistor-capacitor (RC) circuit (Figure 5.1b; Carandini et al., 1997). The voltage across the capacitor,  $V(x, t)$ , is the response of the unit, which represents VSDI response at pixel  $x$ , i.e. the summed activity of a local neural population. Individual neurons are not modeled explicitly.

At each unit, there is an initial step that represents receptive field summation. The spatial receptive field of each unit has a Gaussian weight profile or kernel  $R(x) = \frac{1}{\sigma_R \sqrt{2\pi}} \exp\left(-\frac{x^2}{2\sigma_R^2}\right)$  centered at its location. The result of receptive summation  $A(x, t)$  of the input  $I(x, t)$  provides the driving current to the RC circuit. Since the receptive fields are of the same shape for all the units in a stage,

$$A(x, t) = I(x, t) \otimes R(x), \quad (5.3)$$

where  $\otimes$  denotes convolution. Note that if the input has a Gaussian spatial profile, as in the VSDI experiment,  $A(x, t)$  will also be a Gaussian.

The key property of the model is that the conductance  $g(x, t)$  of the resistor, and hence the dynamics of the circuit, at each unit is not fixed but depends on the average input from a large population. More precisely, the conductance increases from a baseline value with the weighted average  $B(x, t)$  over a local region of the input  $N(x)$  as:

$$(x, t) = g_0(1 + B(x, t)), \quad (5.4)$$

where  $g_0$  is the baseline conductance and  $B(x, t) = k \cdot I(x, t) \otimes N(x)$ . For reasons that will become clear in the next section,  $N(x)$  is called the normalization pool and  $B(x, t)$  the normalization activity. The spatial normalization pool  $N(x)$  is assumed to have a Gaussian weight profile  $N(x)$  centered at the location of each unit. It is assumed to be wider than the receptive field, i.e.  $\sigma_N > \sigma_R$ , so that a larger region contributes to the conductance rather than just the area within the receptive field. The multiplicative factor  $k$  controls the overall strength of normalization.

The membrane potential  $V(x, t)$  can then be described by the RC circuit equation

$$C \frac{\partial V(x, t)}{\partial t} = A(x, t) - g(x, t)V(x, t), \quad (5.5)$$

where  $C$  is the constant membrane capacitance.

### 5.1.3 General behavior of a model stage

One way to illustrate the dynamics of a stage in the model is through a step input that was used in the VSDI experiment:

$$I(x, t) = \begin{cases} J(x), & 0 \leq t \leq t_f \\ 0 & \text{otherwise,} \end{cases} \quad (5.6)$$

where  $J(x)$  is a Gaussian that models the Gabor stimulus and  $t_f$  is the time when the stimulus disappears. During the stimulus presentation, both the driving current  $A$  and the conductance  $g_0(1 + B)$  are constant (Figure 5.1c), and the dynamics of the model simplifies to

$$C \frac{\partial V(x, t)}{\partial t} = A(x) - g_0(1 + B(x)) V(x, t), \quad (5.7)$$

which has the solution:

$$V(x, t) = \frac{A(x)}{g_0(1 + B(x))} \left( 1 - \exp \left( -\frac{g_0(1 + B(x))}{C} t \right) \right). \quad (5.8)$$

Equation 5.8 above simply describes the process of charging a capacitor with time constant  $\frac{C}{g_0(1 + B(x))} = \frac{C}{g(x)}$ , i.e. the conductance and the time constant are inversely related.

#### Rising edge of the response

The key property of the model is that conductance  $g(x, t)$  depends on the average input from a large population. When normalization activity  $B(x, t)$  at a unit is high, conductance is large and the time constant is small. Thus, when normalization activity is high the response can change rapidly to a change in the input. This property can account for much of the dynamics observed in the VSDI responses. At a particular unit, when the stimulus contrast is high, the input amplitude and hence the normalization activity is large, resulting in faster dynamics (Figure 5.1c). This property is consistent with the observed dynamics in the rising edge of the VSDI responses at a particular location for different contrasts.

For a Gabor stimulus, the normalization activity is largest at the center, where contrast is the highest (Figure 5.1c). The response at the center therefore rises at a faster rate than that at the periphery, which again is consistent with the observed properties of VSDI responses. This is an interesting property because the spatial difference in time constants can account for the traveling wave observed at the rising edge even without slow lateral connections that are generally hypothesized to be the cause of the wave (Hirsch & Gilbert, 1991; Murakoshi et al., 1993; Grinvald et al., 1994; Nelson & Katz, 1995; González-Burgos et al., 2000; Telfeian & Connors, 2003).

## Steady state response

When the stimulus is presented long enough, the membrane potential will reach a steady state  $V(x) = \frac{A(x)}{g_0(1+B(x))} = \frac{A(x)}{g(x)}$ . In other words, the gain of the circuit is the inverse of conductance, and therefore the conductance has a divisive (normalizing) effect on the output of the receptive field summation. Since conductance is a function of  $B(x, t)$ ,  $B(x, t)$  is called the normalization activity and the weight profile  $N(x)$  is called the normalization pool. The overall strength of normalization is controlled by the multiplicative factor  $k$  that scales  $B(x, t)$ . Note that, as indicated in Figure 5.1c, the conductance is set instantly by the current value of the normalization pool without any additional time lag or temporal filtering. One way this process might be implemented biologically would be with feedforward inhibition, as reviewed in Chapter 2, that is as rapid or more rapid than the excitation.

To analyze how the steady-state response changes with contrast for the stimuli used in the VSDI experiment, note that for a given unit  $x$ ,  $B(x)$  can be written as  $r(x)A(x)$ . This gives the steady-state response

$$V_s(x) = \frac{A(x)}{g_0(1 + r(x)A(x))}, \quad (5.9)$$

which is a saturating function of  $A(x)$  that approaches  $1/(g_0r(x))$  as  $A(x)$  increases. Such saturation is desirable for modeling the contrast response observed in experiments.

## Falling edge of the response

When the stimulus disappears at  $t_f$ , both  $A$  and  $B$  become zero. This effect leads to the following dynamics:

$$C \frac{\partial V(x, t)}{\partial t} = -g_0 V(x, t), \quad (5.10)$$

which has a simple solution:

$$V(x, t) = V_0(x) e^{-\frac{g_0}{C}(t-t_f)}, \quad (5.11)$$

where  $V_0(x)$  is the response at the time of stimulus offset  $t_f$ . This solution has three important implications. First, the responses at all locations start to decay all at once after the stimulus disappears, regardless of stimulus contrast and  $V_0$ . Second, the responses decay with the same time constant  $C/g_0$  at all locations (Figure 5.1c). Finally, note that the time constant of the rising edge  $C/(g_0(1+B(x)))$  is smaller than  $C/g_0$ . This observation explains why the slopes of the falling edges are shallower than those in the rising edges in the data. The dynamic nonlinearity in the model therefore can account for many of the observed properties of the population responses.

## More general input time course

With the stimuli used in the VSDI experiments, the above analysis of the model's dynamics is exact for the first stage because the time course of the stimulus is a step function. However, in general, the input takes time to build up and fall off. This is the case in particular for the second stage where the input is the response of the first stage. The solution for the membrane voltage  $V(x, t)$  will therefore have a more complex form.

Although in general there is no analytical solution to  $V(x, t)$  for arbitrary input time course, for the stimulus used in the VSDI experiments the three phases of the responses in the second stage can be qualitatively analyzed. Because the spatial profile of the input is unimodal, the normalization activity in the second stage is the largest at the center of the stimulus and with large input amplitude. The rising edge

of the response is therefore fast in these conditions, as it is for a step input. Such unimodal distribution of normalization activity also exists during the falling edge in the second stage because its input, i.e. response in the first stage, decays exponentially at all locations instead of turning off instantly. However, the difference between the falling edges at different locations will be smaller than that of the rising edges because (1) the input falls at the same rate for all locations, whereas there is already a difference in the rising edges of the input, and (2) the responses will all decay at same rate when the input becomes negligible. Finally, the steady-state response in the second stage will also saturate at high input, by the same argument as in Section 5.1.3. As will be shown in Section 5.4.1, the dynamics of the responses in the second stage thus remain similar to those for a step input and are consistent with the observed population responses in V1.

#### 5.1.4 Response transformation between stages

The response  $V(x)$  at pixel  $x$  in the model represents membrane potential, which dominates the VSDI responses. Since neurons communicate through spikes, the responses in the first stage have to be converted into spikes that the second stage receives. As mentioned in Section 4.4, a recent study showed that the VSDI responses can be related to spiking activities by a power function (C. R. Palmer et al., 2008). A similar relationship has also been found between the average membrane potential and the firing rate in single unit recordings (Anderson, Lampl, Gillespie, & Ferster, 2000; Finn, Priebe, & Ferster, 2007). A fixed power function is thus applied to the responses in the first stage and the results are fed into the second stage as inputs:

$$I_2(x, t) = V_1(x, t)^n, \quad (5.12)$$

where the subscripts denotes the stages.

While the stimulus represented in the input sheet can be fed directly to the first stage to provide a reasonably good fit to the data, the predictions shown in this dissertation are for a model with a second fixed power function applied to the activity in the input sheet. This initial nonlinearity is plausible given the accelerating point nonlinearities seen in the earliest levels of the visual system; e.g. the nonlinear relationship between the membrane potential of the photoreceptors and their rate of glutamate release (Witkovsky, Schmitz, Akopian, Krizaj, & Tranchina, 1997) that excites the downstream neurons in the retina.

While the power function accelerates both rising and falling edges, it preserves the relationship between speed and amplitude of responses among different locations. In particular, the falling edge of the response in the first stage still falls at the same rate at all locations:  $(e^{-\frac{t}{\tau}})^n = e^{-\frac{t}{\tau/n}}$ . The Gaussian profile in the input sheet is also preserved:  $(\exp(-\frac{x^2}{\sigma^2}))^n = \exp(-\frac{x^2}{\sigma^2/n})$ . Thus the analytical results presented in this section still apply.

## 5.2 Effects of normalization pool size

When a step input is presented, the response at each model unit rises with a time constant that depends on its conductance. Since conductance is a function of normalization activity, it in turn depends on two factors in the model: (1) the multiplicative factor  $k$  that scales it, and (2) the spatial weighting function of the normalization pool  $N(x)$ . The width of the weighting function is important biologically because it represents the size of the pool of neurons that contributes to the response dynamics at one location. This section discusses how it affects the rising edge and the spatial profile of the response.

Consider a fixed localized input and different Gaussian normalization weighting functions that have the same total weight. If the pool is wide, then the normalization activity will be similar for units near and far from the center of activity. Thus, the difference in the slopes of the rising edges across space will be small. On the other hand, if the normalization pool is small, there will be a large difference in the time constants of different units. Varying the size of the pool thus changes the time courses of the rising-edge responses at different locations. These considerations suggest that the observed difference between the time courses at the different locations can be explained by a feedforward PGC model with an appropriate pool size.

Normalization pool size also influences the spatial profile of the response. Consider a static Gaussian input and its corresponding steady-state response,  $V(x) = A(x)/g(x)$ . If the pool is much wider than the input, then the normalization activity and hence the conductance  $g(x)$  will be the same at all units. In this case, the spatial response profile will simply be a scaled version of the receptive field summation, thus preserving the shape of  $A(x)$ . On the other hand, if the normalization pool is much narrower than the input, then response saturation will occur at a different stimulus contrast for each unit as in the LN model, thus flattening the response profile at high contrasts. As a result, to achieve the contrast-invariant spatial profile observed in the VSDI responses, the normalization pool size has to be at least comparable to the size of the stimulus used.

In summary, the normalization pool size affects both spatial and temporal properties of the responses. Based on these properties, it is possible to estimate the overall pool size and the other parameters from the data of the VSDI experiment. The procedure is described in the next section.

### 5.3 Parameter estimation

The values of the parameters were estimated by fitting the responses in the second stage of the model to the VSDI responses. To reduce the number of free parameters,  $g_0$  is assumed to be 1.0 for both stages because it is effectively a scaling factor of the response and the conductance. The constant delay in the input sheet was chosen to be 20 ms, which was a few milliseconds shorter than the shortest latency seen in the data. The exponent of the power function that converts membrane potential into spikes was chosen to be 2.0, which is similar to what has been found experimentally (C. R. Palmer et al., 2008) and provides a good fit to the data. The same exponent is also used for the input sheet response.

Based on the literature suggesting that the widths of the center and surround in the afferents of V1 are about half of those in V1 (Sceniak, Chatterjee, & Callaway, 2006),  $\sigma_{R,2} = 2\sigma_{R,1}$  and  $\sigma_{N,2} = 2\sigma_{N,1}$ , where the number in the subscripts denote the stage of the model. Furthermore, the width ( $\sigma$ ) of the VSDI spatial profile is assumed to be the result of cascaded receptive field summation and the power function. The value of  $\sigma_{R,1}$  is hence given by

$$\sigma^2 = (\sigma_x^2/2 + \sigma_{R,1}^2)/2 + \sigma_{R,2}^2 \quad (5.13)$$

$$= (\sigma_x^2/4 + 9\sigma_{R,1}^2)/2, \quad (5.14)$$

where  $\sigma_x$  is the width of the stimulus in the input sheet.

Using the measured rising edge time constants  $\tau_c$  at the center location  $c$  and  $\tau_p$  at the periphery that is  $p$  mm from the center, the size of the normalization pool in the second stage  $\sigma_{R,2}$  of the model can be estimated. The procedure gives the lower bound for  $\sigma_{R,2}$ , because it does not take the difference in the

slopes of the input to the second stage into account; if there is already some difference in the input,  $\sigma_{R,2}$  would need to be larger to offset the difference.

From Section 5.1.3,  $\tau_c$  is related to  $B(c)$ :

$$\tau_c = \frac{C}{g_0(1 + B(c))} \quad (5.15)$$

$$B(c) = \frac{\tau}{\tau_c} - 1, \quad (5.16)$$

where  $\tau = C/g_0$ , which is the time constant of the falling edge. Since both  $\tau$  and  $\tau_c$  can be measured from the data,  $B(c)$  can be evaluated to give a numerical value. Similarly,  $B(p) = \frac{\tau}{\tau_p} - 1$  and can be computed.

Note that  $B(x)$  is a Gaussian with width  $\sqrt{\sigma_1^2 + \sigma_{N,2}^2}$ , where  $\sigma_1^2 = (\sigma_x^2/2 + \sigma_{R,1}^2)/2$ , and  $B(c)$  and  $B(p)$  are the values at their corresponding points. By dividing  $B(c)$  by  $B(p)$ , the width of the normalization pool in the second stage,  $\sigma_{N,2}$ , can be estimated:

$$\frac{B(c)}{B(p)} = \frac{1}{\exp\left(-\frac{p^2}{2(\sigma_1^2 + \sigma_{N,2}^2)}\right)} \quad (5.17)$$

$$\sigma_1^2 + \sigma_{N,2}^2 = \frac{p^2}{2 \ln\left(\frac{B(c)}{B(p)}\right)} \quad (5.18)$$

$$\sigma_{N,2} = \sqrt{\frac{p^2}{2 \ln\left(\frac{B(c)}{B(p)}\right)} - \sigma_1^2}. \quad (5.19)$$

The remaining free parameters that need to be estimated are  $C_1$ ,  $C_2$ ,  $k_1$ , and  $k_2$ . First, the steady-state contrast response function of the model is fitted to the data by minimizing the sum of the squared error. This step enabled  $k_1$  and  $k_2$  to be determined separately from  $C_1$  and  $C_2$ , because the capacitances do not affect the steady-state response of the model. After that, the normalization strengths,  $k_1$  and  $k_2$ , were held fixed, while the capacitances were estimated by fitting the slopes of the rising and falling edges at different locations and stimulus contrasts simultaneously.

## 5.4 Simulation of VSDI responses

The values of the parameters obtained in the above procedure were  $\sigma_{R,1} = 0.983$  mm,  $\sigma_{N,1} = 1.386$  mm,  $C_1 = 3.19$ ,  $C_2 = 2.3$ ,  $k_1 = 1520$ , and  $k_2 = 2$ . The cortical magnification factor measured in this chamber is about 3mm/deg (C. R. Palmer et al., 2008). With this set of parameters, the model was simulated for a 20 mm long strip (extending the black rectangular region in Figure 4.2c) using the Matlab function *ode45()*.

### 5.4.1 Results of the simulation

Figure 5.2a plots the spatial profiles of the peak responses in the second stage of the model for different input contrasts. Consistent with the VSDI responses, the widths of the profiles are all the same (Figure 4.2 and Y. Chen et al., 2006, 2008). Note that profiles will only be contrast-invariant in the model for stimuli with sizes that are smaller or comparable to the receptive field of the V1 units; due to saturation, profiles for large stimuli will change shapes and widths as a function of contrast. The contrast response function of the model is plotted in Figure 5.2b, which provides a good fit to the data ( $r^2 = 0.98$ ).

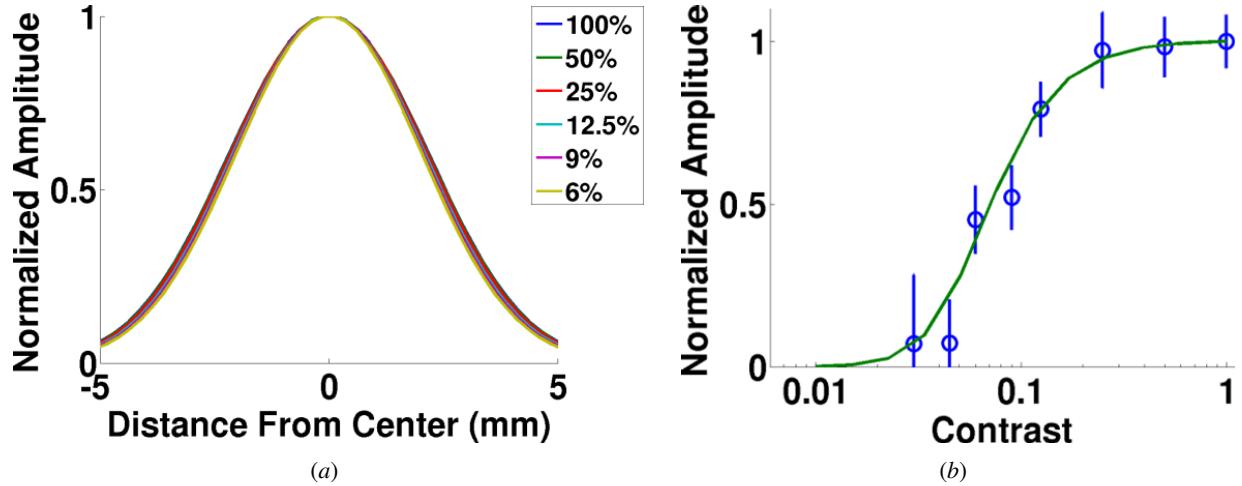

Figure 5.2: **Peak responses of the second stage in the model.** (a) Normalized spatial profile of the peak responses. The widths of the profiles are the same for different contrasts, which is consistent with the VSDI responses (Y. Chen et al., 2006, 2008). (b) Normalized contrast response function at the center. Circles are the responses from the data (Figure 4.2e). The quality of fit is high ( $r^2 = 0.98$ ). The model therefore captures the essential properties of the peak responses observed in the data.

Figure 5.3 shows the space-time plot of the responses of the second stage in the model for different contrasts, using the same format as Figure 4.4. The model captures qualitatively the observed spatiotemporal properties of the responses. For each contrast, (1) the rising edge latencies ( $t_{10}$ ) at different locations are similar, with a maximum difference of 2 ms, and (2) the slope of the rising edge becomes shallower as distance from the center increases. For each location, as contrast increases, (3) response latency decreases, and (4) the rising edge becomes steeper. Finally, for all contrasts and locations, (5) latencies and slopes of the falling edges are similar (< 2 ms difference). Although there are some minor discrepancies at low contrast, e.g. the difference in the slopes of the rising edges across locations is smaller than the data, it is remarkable that such a simple model can account for most of the properties of the population responses in both time and space.

## 5.5 Relative normalization strengths in the different stages

In the PGC model, normalization (contrast gain control) operates in the retina, LGN and in V1, as it does in the primate visual system. There are many nonlinear properties of single unit responses in the retina and LGN, such as phase advance of response at high contrast (Shapley & Victor, 1978; Victor, 1987), contrast saturation (Bonin et al., 2005), and size tuning (Bonin et al., 2005; Sceniak et al., 2006), that can be explained by gain control. These nonlinearities are also observed in V1. It is therefore possible that gain control before V1 contributes significantly to the response nonlinearities in V1. The main question is what the relative strength of the normalization in the different stages of visual processing is. It is an open and important question that is difficult to answer directly by empirical experiments.

This question can be addressed using the PGC model by considering the parameters  $k_1$  and  $k_2$  that set the normalization strengths, and hence the degrees of nonlinearity, in the two stages of the model. As it turns out, the stimuli used in the VSDI experiment are not sufficient to discriminate between hypotheses

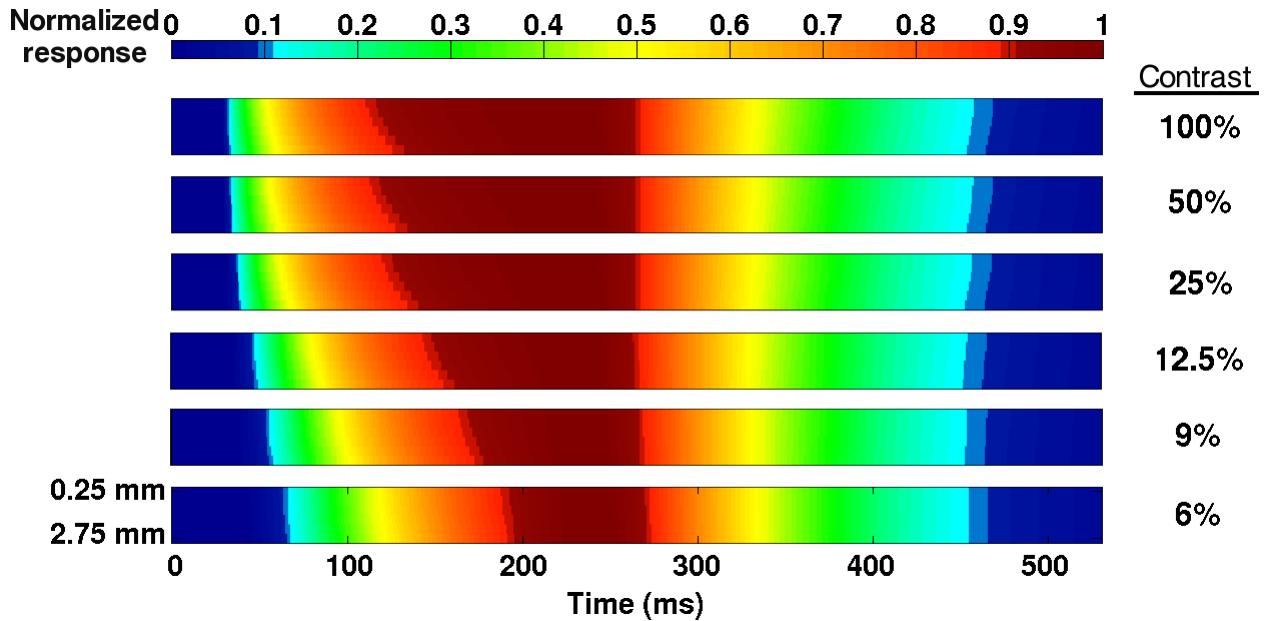

Figure 5.3: **Spatiotemporal responses of second stage in the model.** The properties of the responses are similar to the observed data shown in Figure 4.4, suggesting that population gain control may be a general mechanism of visual processing.

concerning relative normalization strength. However, by varying the size of the stimulus it is possible to estimate the relative contributions of normalization in the first stage (retina to layer 4 of V1) and the second stage (superficial layers of V1): The relative strength of the normalization in the two stages has a large impact on the expected size tuning of V1 responses. Figure 5.4 shows the predicted response amplitude at the center of the activated region in the superficial layers of V1 as a function of stimulus size. The contrast of the Gabor stimulus is 100%. Each curve in the figure is for a different strength of normalization in the first stage relative to the total strength in both stages of the model, i.e.  $k_1/(k_1 + k_2)$ . The curves have been scaled so that response is 1.0 for the Gabor size used in the VSDI experiment ( $\sigma = 0.167^\circ$ ). When normalization only occurs in the first stage of the model (100%), the response increases with stimulus size because the second stage is linear (i.e. no normalization). As the normalization in the second stage becomes stronger (the other curves), the relative response to the larger stimuli, e.g.  $\sigma = 1^\circ$ , decreases, because normalization has a divisive effect on the input from the first stage. For the parameter values that can fit the VSDI responses, further decrease of the relative normalization weakens size tuning.

In an additional biological experiment, the VSDI responses to 100% contrast Gabor stimuli with  $\sigma = 0.167^\circ$  and  $1^\circ$  were measured. The red dots in Figure 5.4 plot the relative responses to the two stimuli. The peak response to the large stimulus is about 7% less than that of the small stimulus, which is consistent with a strong (99%) normalization in the first stage of the model. This pair of normalization strengths was used to obtain the simulation results shown in Figure 5.2 and 5.3.

This surprising result suggests that the nonlinearity observed in the data may be mostly implemented before the superficial layers of V1 where the VSDI signals are measured. It illustrates nicely how computational model can be used not only to replicate the behavior of the responses, but to gain new insight about visual processing.

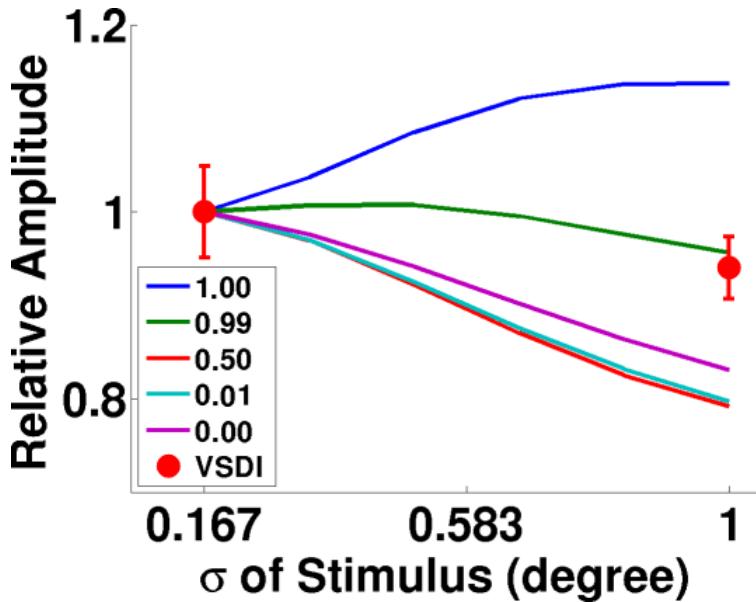

Figure 5.4: **Predictions of the size tuning curves of five example combinations of normalization strengths.** Each curve represents a different combination of normalization strengths, labeled by the proportion of normalization in the first stage ( $k_1/(k_1 + k_2)$ ). The contrast of the stimulus is 100% and the response is measured at the center. The red dots plot the normalized responses obtained in the VSDI experiment for two stimulus sizes. The reduction of VSDI response to the large stimulus is small, which is consistent with a strong normalization in the first stage of the model.

## 5.6 Discussion

The complex spatiotemporal dynamics of the population responses in V1 can be captured by a simple PGC model. At the core of this model is divisive population gain control. Although it is a functional model rather than a detailed low-level biophysical model, the necessary neural substrate should exist to support such a mechanism. In this section, issues of modeling population responses and possible biological implementation of divisive population gain control are discussed. The new insights that the PGC model provides, combined with quantitative analysis of population responses, will also be reviewed.

### 5.6.1 Modeling population responses

The response at each pixel in VSDI corresponds to the average activity of a large neural population. The goal of this dissertation is to understand the dynamics of this average signal. Although it is possible to build models that include the variations of responses within the population, it would not be possible to verify them given the averaged nature of the data. Furthermore, the size of the aggregate at each pixel is quite large (many thousands of neurons) which should produce fairly stable and similar dynamics across pixels, justifying using a homogeneous population for each stage of the model.

On the other hand, the averaged population responses may not be what the individual downstream neurons receive. It is thus an open question how the downstream population responses depend on the variations in the input. The good fit of the PGC model to the data suggests that at least for V1, the population responses are mainly determined by the averaged activity in the input. More studies are required to investigate if this property holds in higher level areas.

## 5.6.2 Possible implementation of divisive population gain control

A central idea of the PGC model is that the gain is controlled through division. A key question is therefore: How can such division be achieved in a neuron? It is possible that division can be implemented by combining different biophysical mechanisms at different scales (Kayser, Priebe, & Miller, 2001; Carandini, 2004). At the level of individual neurons, local nonlinearities such as synaptic depression (Abbott, Varela, Sen, & Nelson, 1997; Tsodyks & Markram, 1997) have a divisive effect on the presynaptic activity, but these mechanisms are unlikely to account for the long-range effects that are observed in the data. Long-range feedback and lateral connections with inhibitory interneurons (McGuire, Gilbert, Rivlin, & Wiesel, 1991; Gilbert, Hirsch, & Wiesel, 1990) could deliver the normalization signals at the population level. Their combined effect could be represented by the weighting function of the normalization pool in the model.

Another key question is: Where do the signals that control the gain come from? In the feedforward implementation which is illustrated in Figure 5.1a, the gain of the individual neuron is computed at the same level as its input, and is provided to the neuron at the same time as the excitation. Alternatively, in a feedback implementation, the gain is computed from the output of the neuron and its neighbors. In this case the gain computation can occur either at the same level, or potentially even in a subsequent stage that then sends fast feedback to this level. While a feedforward circuit appears to be the simplest and most parsimonious implementation of gain control, a mechanism that involves very rapid feedback, potentially through a specialized subset of the neurons with fast dynamics, cannot be ruled out. Additional experiments are needed to address this question.

A phenomenon related to gain control is the decrease of noise in the membrane potential at high stimulus contrasts in simple cells of the cat (Finn et al., 2007). A reduction in noise can effectively contribute to gain control by making the membrane potential less likely to cross spike threshold at high contrast; however, noise reduction may itself be the result of some form of gain control (in many systems lowering gain lowers noise). Hence, further investigations will be required to understand the relationship between contrast gain control and membrane-potential noise.

Another major assumption of the model is that the conductance changes instantaneously with the input. While it may not be plausible for conductance to jump immediately from one level to another, there is evidence suggesting such a change occurs within milliseconds. In monkey and cat V1, contrast gain control was fully expressed within the first 10 ms after response onset (Albrecht, Geisler, Frazor, & Crane, 2002). This observation suggests that conductance changes faster than this time window. Simulations of a modified model where the conductance changed with a time constant of 10 ms showed that there was no qualitative difference in the responses. The basic instantaneous model thus provides a reasonable approximation to realistic timing for the change.

## 5.6.3 Relationship between the responses of a single neuron and a neural population

The VSDI responses reported in Section 5.5 have weak size tuning, which are unexpected given the strong suppressive effect of large stimuli observed in single units in V1 (Sceniak, Ringach, Hawken, & Shapley, 1999; Sceniak, Hawken, & Shapley, 2001; Cavanaugh, Bair, & Movshon, 2002; Levitt & Lund, 2002). One possible explanation is that the VSDI signals at each pixel represent the summed activity from thousands of neurons. Such large populations can exhibit emergent properties that are different from those of individual neurons.

This idea is illustrated nicely in the size tuning behavior in the model. When all of the normalization

occurs in the first stage of the model, then the units in this stage have strong size tuning. However, when these units are pooled linearly to produce the response of a unit in the second stage, this unit has much weaker size tuning. The reason is that as the size of the stimulus increases, some of the units in the first stage that provide input to this unit decrease their responses due to surround suppression, while others increase their responses, because the stimulus now enters the center of their receptive field. The net effect of increasing the stimulus size is therefore much weaker in the second-stage unit than in the individual units in the first stage that provide input to it.

#### 5.6.4 Importance of combined quantitative analysis and modeling

To understand the functional role of a neural substrate, e.g. lateral connections, it is important to relate the substrate's biophysical properties (e.g; slow propagation speed Hirsch & Gilbert, 1991; Murakoshi et al., 1993; Grinvald et al., 1994; Nelson & Katz, 1995; González-Burgos et al., 2000; Telfeian & Connors, 2003) to its effect on neural activity (e.g; delayed propagation of activity in the cortex). However, the mere presence of the expected effect in neural responses does not imply that the substrate is the underlying cause. The analysis of the latency of the VSDI responses illustrates this well. While it is intuitive to attribute the spatially increasing time to half peak of the rising edge as evidence for propagation through slow lateral connections in V1, the quantitative analysis of the rising edge latencies and computational model suggest otherwise. The similarity in the rising edge latencies across space is inconsistent with a significant contribution from slow lateral propagation, and the difference in slopes can be explained by a simple feedforward population gain control model that also predicts many other properties of the responses. Thus, this dissertation demonstrates the value of quantitative analysis and computational modeling in testing hypotheses regarding the biophysical and anatomical factors underlying neural population activity.

### 5.7 Conclusion

The rich spatiotemporal dynamics observed in the responses place strong constraints on computational models of V1. Interestingly, a simple canonical normalization-based PGC model defined in this chapter can account for such dynamics.

The PGC model was also used to address the outstanding question regarding the degree to which nonlinearities in V1 responses are inherited from its inputs. The PGC model predicts how the responses to a large stimulus depend on the nonlinearity in V1 and its input. Results from an additional VSDI experiment that varied stimulus size were consistent with the hypothesis that most of the response nonlinearity observed in V1 is inherited from its input. This result suggests that most of the gain control for small localized stimuli may be implemented before the superficial layers of V1 (i.e. in the retina, LGN, and/or layer 4 in V1). Potential advantages of implementing a large component of the contrast gain control before the superficial layers in V1 is that it could help preserve tuning in the retina and LGN (as well as in cortex).

Given the limited dynamic range of spiking activity, population gain control is a simple and effective mechanism that can maintain the sensitivity and tuning of neurons over a large range of sensory stimuli. It is therefore possible that population gain control operates in most, if not all, sensory cortical areas. If so, the population dynamics reported here in V1 may be observed in many other areas, and the corresponding pathways could be simulated by a cascade of PGC models.

The PGC model can account for the spatiotemporal dynamics of the population responses for a small localized stimulus. However, such stimuli rarely occur in real world. In the next chapter, more complicated

spatial stimuli consisting of two elements will be used to validate the model by comparing its predictions with the VSDI responses.

# Chapter 6

## Spatial Interactions Between Visual Stimuli

As shown in the previous chapter, the PGC model can account for most of the spatiotemporal properties of V1 population responses for a small localized stimulus. Although such stimuli are useful for characterizing the response dynamics, they rarely occur in the real world. This chapter discusses the predictions of the PGC model for V1 population responses to more complicated spatial stimuli that contain two elements. The model was used to pinpoint a small set of stimuli that was expected to be most informative for characterizing the interactions between two elements. These stimuli were subsequently used in VSDI experiments. The properties of the VSDI responses are largely consistent with the model's predictions, suggesting that population gain control is a general mechanism for visual processing. The responses for these stimuli in the model were also used to predict how the interactions can affect perception, providing insight into how neural responses may be decoded in the brain.

### 6.1 Motivation

The PGC model can account for the complex spatiotemporal dynamics of the V1 population responses to a single Gabor stimulus on a uniform background. While such stimulus is widely used for characterizing the responses in the visual cortex, it is very different from natural scenes, which contain much more variations in local contrast. To understand visual processing in a natural setting, it is important to extend the studies of the model and neural response to more complicated stimuli. A systematic way for conducting such studies is to increase the number of Gabor elements and measure the neural response as the features of the stimulus vary.

In fact, there is a long history of using such stimuli to study the response of single neurons in the visual cortex (Knierim & van Essen, 1992; Kapadia, Ito, Gilbert, & Westheimer, 1995; Polat, Mizobe, Pettet, Kasamatsu, & Norcia, 1998; see Angelucci, Levitt, & Lund, 2002 for a review). Responses to a Gabor element were found to be modulated by the surrounding Gabor elements. When a center high-contrast element is flanked by other elements with the same contrast, response to the central element in V1 cells is usually smaller than the response to the central element alone, even though the surrounding elements do not elicit any response in these cells (Knierim & van Essen, 1992). On the other hand, when these elements are at low contrast, the response to the central element is facilitated (Kapadia et al., 1995). There are hence interactions between the elements that modulate the responses.

The major limitation of these previous studies is that only the response at a single location can be recorded; usually the center of an element is used. The effect of interaction on the responses at any other

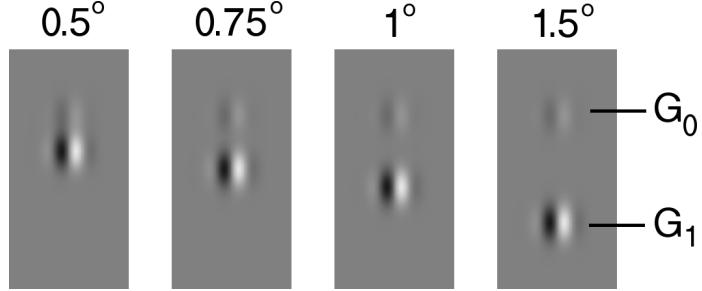

Figure 6.1: **Stimuli for studying interactions between elements.** A stimulus consists of two Gabor elements,  $G_0$  and  $G_1$ , that are aligned vertically. The location of  $G_0$  is fixed while the separation between the elements, which is measured by the distance between their centers in visual angle, can vary. The contrasts of the two elements can also vary independently. There are thus three features that can be changed in such stimuli. Four example stimuli with different separations are shown. Such stimuli are represented by their one-dimensional contrast envelopes across the center of the elements. They were used both with the model and in a set of VSDI experiments.

locations is therefore unknown. While it may be reasonable to assume that the responses to the surrounding elements are symmetric, there is no simple way to estimate the responses at the locations in between the elements. The spatial distributions of the population responses are therefore unknown for multi-element stimuli.

Another limitation with physiological experiments is that only a limited number of trials, and hence stimuli, can be run, whereas there is theoretically an infinite number of feature combinations even for only two elements. It is therefore impossible to explore the whole feature space of the stimulus experimentally, and potentially interesting interactions will be missed.

To address these problems, the PGC model was used to predict the spatial responses for two-Gabor stimuli over a large range of feature combinations.

## 6.2 Interaction of two elements

In this section, stimuli consisting of two Gabor elements of the same size are studied. The model's predictions on the spatial responses will be discussed first, followed by the results of VSDI experiments. The predictions of the model are consistent with the VSDI responses, suggesting that population gain control is a general mechanism of visual processing.

### 6.2.1 Input to the model

As in the previous chapter, the stimuli used in this chapter are stationary. The input stimulus of the model consists of two Gaussian elements,  $G_0(x)$  and  $G_1(x)$ , each representing the contrast envelope of a Gabor element in the visual space (Figure 6.1). The center of  $G_0(x)$  is fixed at location 0, while  $G_1(x)$  can be at any position along the  $x$ -axis. The two Gaussians have the same width, but their amplitudes (contrasts in visual space) can be varied independently. More precisely, the activity of the input layer during stimulus presentation is

$$V_{in}(x) = \min(G_0(x) + G_1(x), 1) \quad (6.1)$$

$$= \min(c_0 G(0, \sigma) + c_1 G(s, \sigma), 1), \quad (6.2)$$

where  $c_0$  and  $c_1$  are amplitudes of  $G_0$  and  $G_1$ , respectively,  $G(a, b)$  is a Gaussian with unit amplitude centered at  $a$  with width  $b$ , i.e.  $G(a, b) = \exp(-\frac{(x-a)^2}{2b^2})$ , and  $\min(a, b)$  is a function that returns the minimum value of  $a$  and  $b$ . This function is necessary because the activity of the input layer represents the contrast envelope, which cannot be greater than 1.0. In physiological experiments, the sum of the contrasts of the two elements is kept below 100% and hence only a subset of the stimuli defined in Equation 6.2 are used. However, for completeness, the results presented in this chapter will include all possible combinations of contrasts.

As a first step, the model does not depend on the orientation of the stimuli. Extending the model to take orientation-related signals into account is a logical future step that will be discussed in Chapter 8. However, as will be shown in Section 6.2.4, the model can account for most of the interactions observed in the VSDI responses for a large range of stimulus configurations, suggesting that the responses are dominated by stimulus contrast.

### 6.2.2 Qualitative analysis of the model

One of the most important questions of the interactions between the elements is how the spatial responses differ from those of the individual elements. Although the model does not have closed-form solutions for such stimuli, its behavior can be understood qualitatively by considering the steady state response at the center of the element  $G_0$ , i.e. at location 0.

When the separation between the two elements is large, the activity due to  $G_1$  does not fall into the receptive field and the normalization pool of the unit at location 0. The response at this location is therefore unaffected by  $G_1$ . As the separation decreases, part of the activity of  $G_1$  will enter the normalization pool of this unit, but not the narrower receptive field. In other words, the receptive summation at location 0,  $A(0)$ , will not be affected while the normalization activity at this location,  $B(0)$ , increases. As a result, the steady state response  $V_s(0)$  will be smaller than that for the stimulus with  $G_0$  alone because  $V_s(x) = \frac{A(x)}{g_0(1+B(x))}$  (Section 5.1.3). The response at location 0 is therefore suppressed by the addition of the element  $G_1$  at such distance.

With further decrease in the separation, more and more activity of  $G_1$  enters the normalization pool of unit 0. The suppression therefore becomes stronger. Below a certain separation, the activity of  $G_1$  will fall into both the receptive field and the normalization pool of unit 0, and  $A(0)$  and  $B(0)$  will increase. Because of the receptive field's narrower width,  $A(0)$  increases more than  $B(0)$  as the separation decreases, and this increase counteracts the suppression. Below certain separation, the suppression is completely overcome, leading to a larger response than that for the stimulus with  $G_0$  alone. A special case is when the separation is zero. The two elements overlap and their contrasts simply add up, resulting in a larger response. The effect of interactions therefore depends on the separation between the two elements.

The contrasts of the elements can also affect the interaction. If the contrast of  $G_0$  is high, its response will not be affected significantly by a low-contrast  $G_1$ . The increase in  $A(0)$  and  $B(0)$  induced by  $G_1$  is small relative to those due to  $G_0$  and hence the change in response will be small. On the other hand, the response to a low-contrast  $G_0$  will be modulated strongly by  $G_1$  because the change in  $A(0)$  and  $B(0)$  can be substantial.

In summary, the PGC model predicts that the interactions between the elements depend on their separation and contrasts. When the separation is large, the interactions will be suppressive. The suppression increases and then decreases as the separation becomes smaller. With further reduction in separation, the interactions turn into facilitatory. These effects are the strongest for an element at low contrast.

### 6.2.3 Results of simulation

This section shows the predicted V1 population responses of the PGC model for the two-element stimuli. In particular, how the spatial responses are affected by different combinations of contrasts and separation are discussed.

#### Model simulation

The PGC model was simulated using the two-element stimuli as input. Stimuli that contained only one of the elements were also used to compare the prediction responses. The location of  $G_1$  is always to the left of  $G_0$  (negative  $x$ -coordinates). The parameters of the model were:  $\sigma_{R,1} = 0.7$  mm,  $\sigma_{N,1} = 1.02$  mm,  $k_1 = 1089$ , and  $k_2 = 2$ . They are different from those used in the previous chapter to match the VSDI responses of the two-element stimuli, which will be presented in the next section. Since the VSDI experiments were carried out with a different animal from the one used in the previous chapter, the change in parameters may reflect the individual differences of the brains. These new values do not qualitatively affect the properties of the model's responses for the stimuli used in the previous chapter.

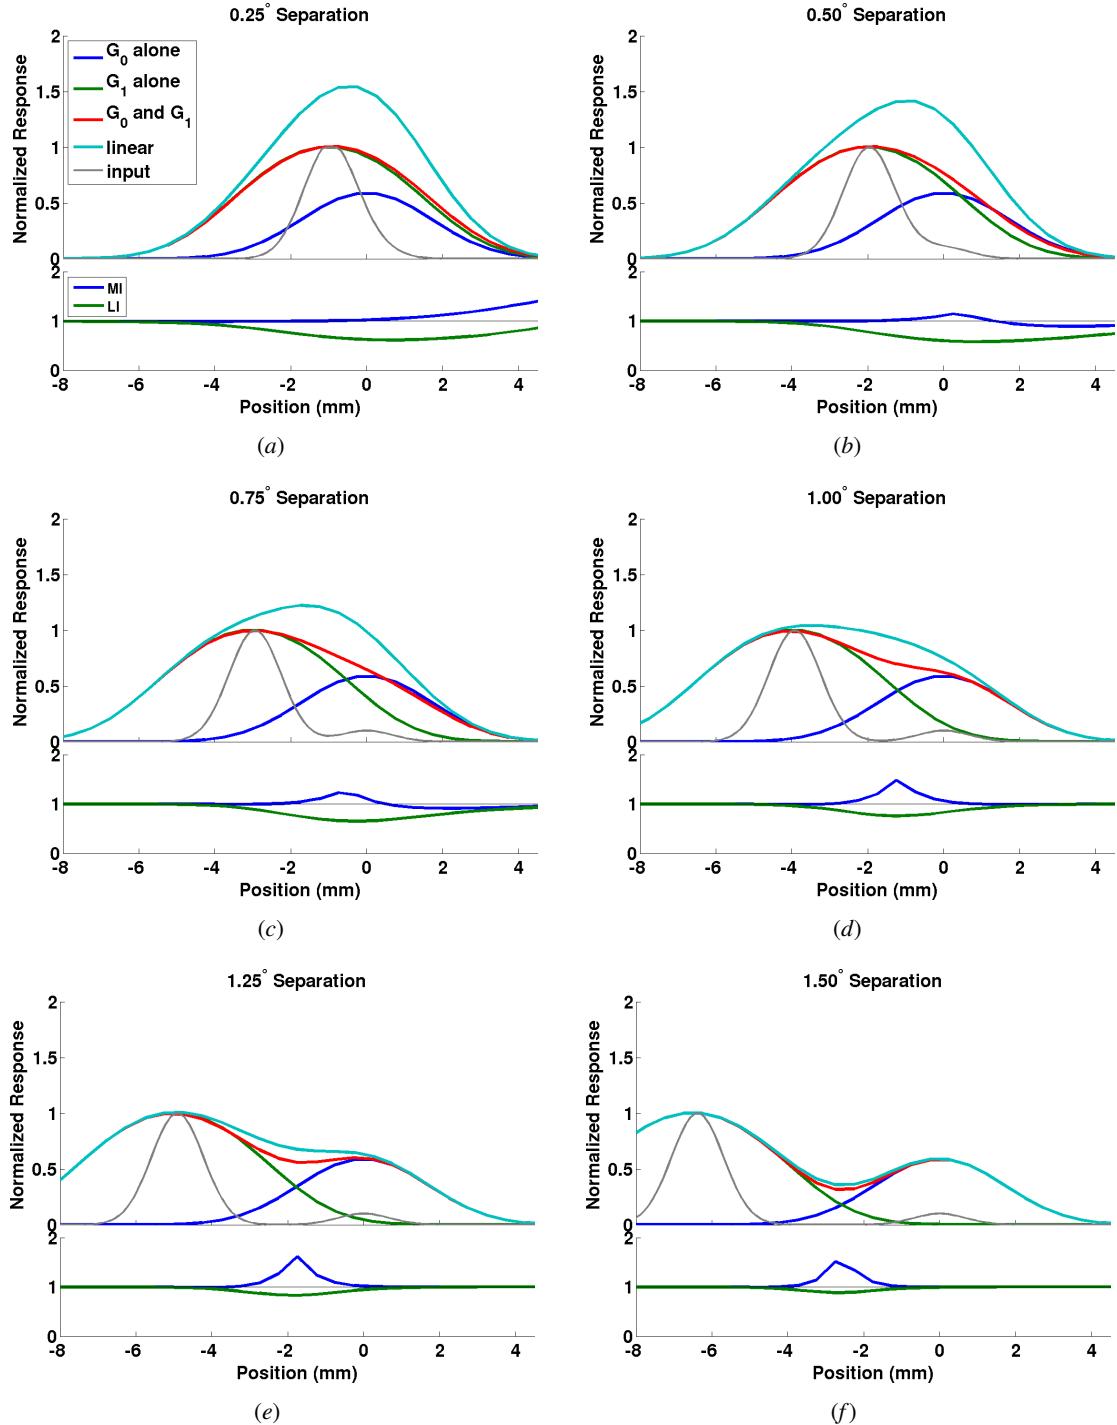

To illustrate the interactions, results of three example contrast combinations for different separations will be first presented, followed by a summary of the interactions at the center location for a large range of combinations of the stimulus features.

#### Interaction of a high-contrast element and a medium-contrast element

Figure 6.2 shows the spatial profiles of the model's peak responses when the separation between a 10% contrast  $G_0$  and a 100% contrast  $G_1$  is varied. In addition to showing the response profile for the two-element stimulus in each subplot, profiles for the stimuli that contain either one of the elements are also shown to illustrate how the responses are modulated by the interactions of the elements. Furthermore, the linear prediction of the responses for the two-element stimulus is plotted by simply summing up the responses to the single-element stimuli. The linear prediction serves as a benchmark for gauging the interactions, and is commonly employed in the analyses of neural responses. To compare the responses and the linear prediction at different locations, their ratio, termed Linearity Index ( $LI$ ), is plotted in the subplot under each spatial profile. In other words,  $LI(x) = V_{\text{both}}(x)/(V_{G_0}(x) + V_{G_1}(x))$ , where  $V_{\text{both}}(x)$ ,  $V_{G_0}(x)$ , and  $V_{G_1}(x)$  are the responses to the stimuli containing both elements,  $G_0$  alone, and  $G_1$  alone, respectively. Similarly, the responses can be compared to the maximum of those for single-element stimuli using a Maximum-Rule Index ( $MI$ ), i.e.  $MI(x) = V_{\text{both}}(x)/\max(V_{G_0}(x), V_{G_1}(x))$ . If  $MI$  is larger than 1 at a particular location  $x'$ , the interaction is facilitatory, otherwise it is suppressive to at least one of the  $V_{G_0}(x')$  and  $V_{G_1}(x')$ .

One of the prominent properties of the spatial profiles in Figure 6.2 is that the responses to the two-element stimuli (red curve) are significantly smaller than or equal to the linear prediction (cyan curve) for separations less than  $1.5^\circ$ . This result suggests that the interactions are not a simple summation. While the interactions seem to always produce subadditive responses, as will be shown in Figures 6.4 and 6.5, for a narrow range of contrasts and separation combinations, it is possible for the response to be larger than the linear prediction. For separation larger than  $1.5^\circ$ , the elements are too far apart to have any effect on each other and there are no interactions between them.

As discussed above, the response to the high contrast  $G_1$  is only slightly affected by the addition of the lower contrast  $G_0$ : The red curve (two-element stimulus) largely overlaps with the green curve ( $G_1$  alone) for all locations except those in the proximity of  $G_0$ .

**Figure 6.2: Spatial profiles of the model responses for stimuli consisting of a 10% contrast element and a 100% contrast element.** Each subfigure is for a particular separation between the elements. The top graph in each subfigure shows the spatial profiles of the peak responses (red) to the two-element stimulus (gray). The response profiles of the individual elements when they are presented alone at their corresponding locations are also plotted (blue and green). The sum of the profiles for individual elements forms the linear prediction (cyan). The bottom graphs in the subfigures show the  $MI$  and  $LI$  indices across space. The predicted interactions of these two elements are subadditive ( $LI < 1$ ), and can be both facilitatory ( $MI > 1$ ) and suppressive ( $MI < 1$ ). The strongest effect usually occurs at the middle location between the elements and not at the center of an element. This prediction suggests that only measuring the response at the center of an element, as in most previous physiological experiments, may not be effective and sufficient to characterize the effect of interactions.

On the other hand, the responses for  $G_0$  are significantly modulated by the presence of the high-contrast  $G_1$ . When the separation is very small ( $0.25^\circ$ , Figure 6.2a), the two elements largely overlap. The high-contrast  $G_1$  therefore has a dominating contribution to the receptive field summation and normalization activity, resulting in a profile that is nearly identical to that when only  $G_1$  is presented. Therefore, if the profile of the peak responses is used in the brain to determine the spatial distribution of contrasts in the visual stimulus,  $G_0$  will be masked by  $G_1$  and become invisible. As  $G_1$  moves away, its influence on these two quantities wanes. The responses around  $G_0$  hence become more and more similar to the response profile when  $G_0$  is presented alone. Note that the responses at the positive side of  $G_0$  are suppressed by  $G_1$  when it is  $0.5^\circ$  to  $0.75^\circ$  away because of the higher normalization activity it causes at these locations (Figures 6.2b and c). Interesting interactions therefore occur when the other element is at a much higher contrast.

One important prediction that can be readily observed from the peaks and troughs of  $MI$  and  $LI$  is that the maximum effects of interactions do not occur at the center of the elements most of the time; instead they lie in between the centers. This prediction suggests that measuring the local responses at the center only, as in most of the previous physiological experiments studying element interactions, may not be effective and sufficient. Techniques that measure neural responses over a large region at high spatial resolution, such as VSDI, are required to understand the interactions between the elements.

### Interaction of high-contrast elements

Figure 6.3 shows the profiles for stimuli consisting of elements at 25% contrast, at which the VSDI responses start to saturate (Figure 4.2). Similar to the results discussed above, the responses are smaller than the linear prediction. When the elements are close to each other ( $0.25^\circ$  to  $0.5^\circ$ ; Figures 6.3a and b), the responses on the sides of the profile are suppressed. The suppression is weak because the increase in normalization activity is relatively small compared to the receptive field summation, which is large because the elements are at high contrasts. On the other hand, the responses in the middle between the two elements are enhanced. This enhancement is mainly due to the greater receptive field summation than those for the single elements at these locations and the weak normalization in the second stage of the model. Such enhancement remains effective as the separation increases, while the suppressive effect at other locations stays small. The interaction is therefore winner-take-all at most locations except those between the elements.

### Interaction of low-contrast elements

As the other end of the spectrum, Figure 6.4 shows the response profiles when both elements are at 5% contrast. Since the PGC model is fairly linear at low contrast, the profiles for the two-element stimuli are similar to the linear prediction. One interesting property is that when the separation is very small ( $0.25^\circ$ ; Figure 6.4a), the responses are larger than the linear prediction at many locations. This superadditive behavior is due to the overlap between the elements, which increases the local contrast. Because the corresponding portion of the contrast response function is expansive (Figure 5.2), the response will be greater than the linear prediction. Extending this argument, the model predicts that superadditivity can only be observed when the local sum of the contrasts of the two elements is less than about 10% because the slope of the contrast response function is smaller than 1 at higher contrasts. In addition, the separation has to be small such that there is significant overlap to increase the local contrast. Therefore, there is only a small range of contrasts and separation that results in superadditivity and most combinations will produce a response that is less than the linear prediction.

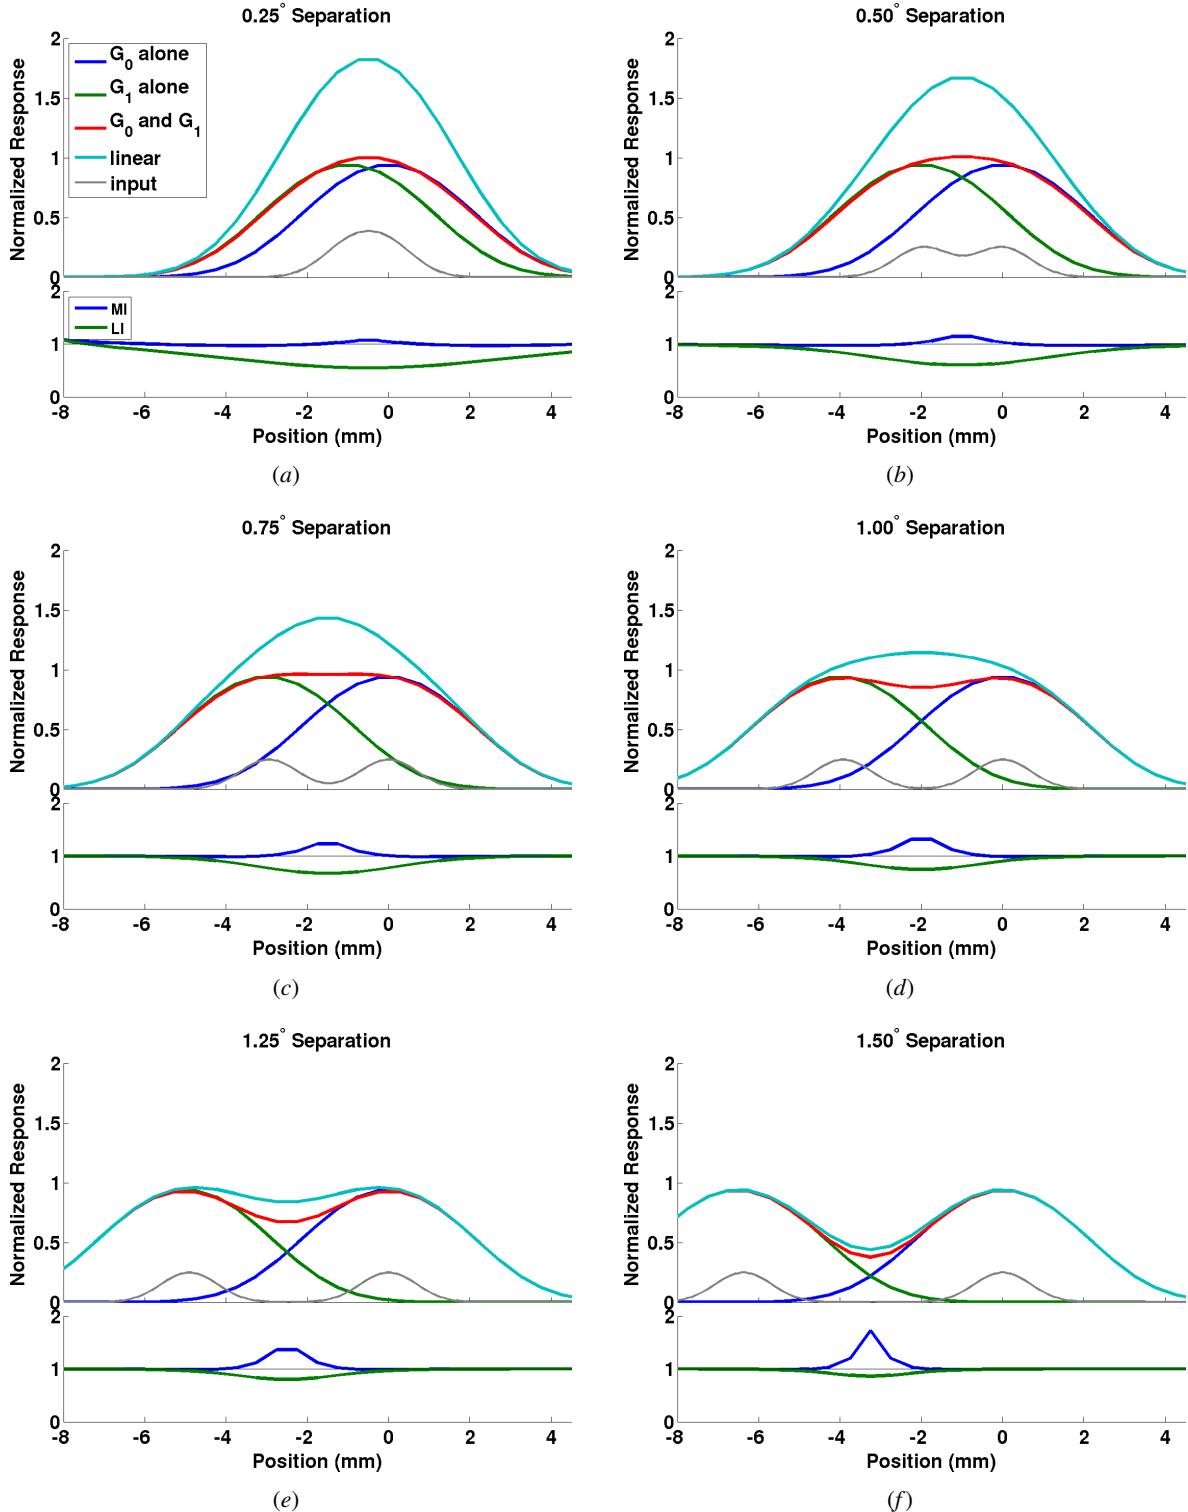

Figure 6.3: **Spatial profiles for stimuli containing 25% contrast elements.** For most separations and locations, the index *MI* is close to one. In other words, the interaction is winner-take-all, which also implies subadditivity for locations that are activated by both elements.

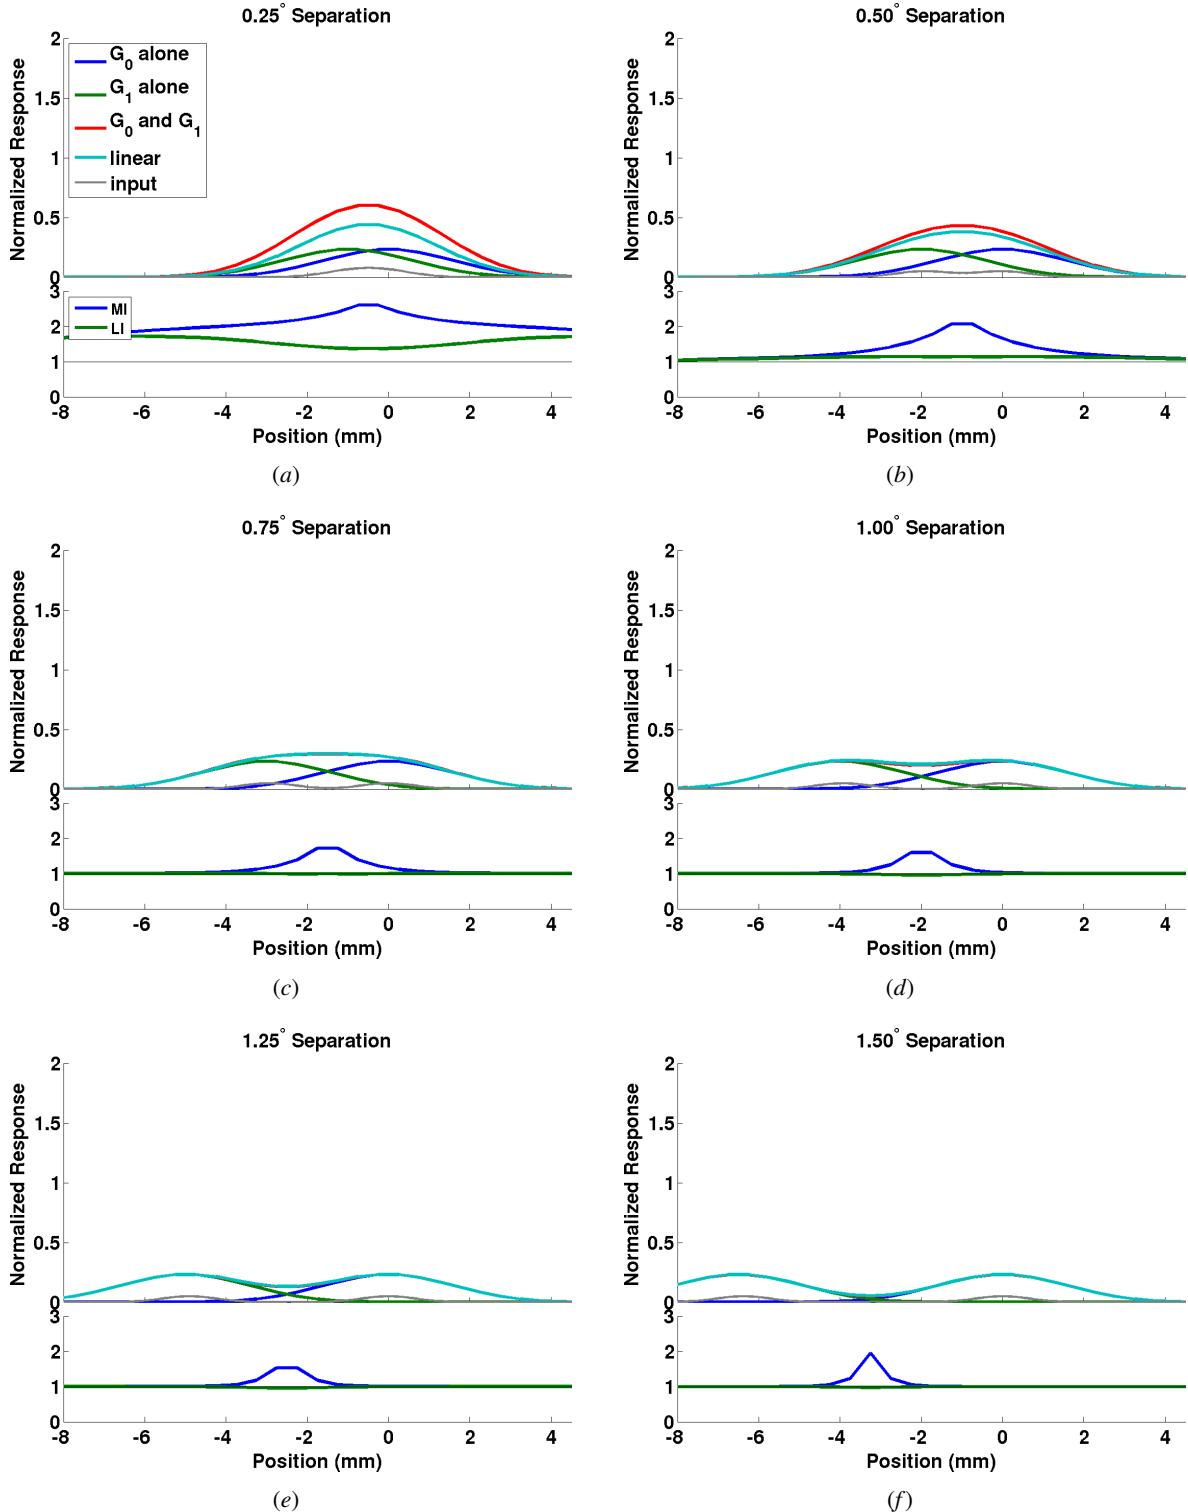

Figure 6.4: **Spatial profiles for stimuli containing 5% contrast elements.** When the elements are close to each other ( $\leq 0.5^\circ$ ), the interaction is superadditive. Such strong interaction weakens and becomes mostly linear as the separation increases. Due to the low input amplitude, interaction mainly occurs in locations between the elements.

## Interaction at the element center

The examples shown in the above sections only cover a few samples in the three-dimensional feature space. To summarize the effects for a large range of feature combinations, the interaction at a particular location can be divided into six regimes using the  $MI$  and  $LI$  indices:

**$MI < 1, LI < 1$**  The response is less than at least one of the responses for a single element ( $MI < 1$ ).

Hence the interaction is suppressive. Note that  $MI < 1$  implies  $LI < 1$  because  $\max(A, B) \leq A+B$  for non-negative  $A$  and  $B$ .

**$MI = 1, LI < 1$**  The response is the same as the largest of the two single-element responses ( $MI = 1$ ).

Because  $LI$  is less than  $MI$ , the other single-element response is greater than zero at that location. This regime is interesting because the interaction is winner-take-all.

**$MI = 1, LI = 1$**  Because  $MI = LI$ , one of the single-element responses is zero. Although the interaction is also winner-take-all ( $MI = 1$ ), there is actually no interaction between the elements.

**$MI > 1, LI < 1$**  The response is larger than any of the single-element response ( $MI > 1$ ). However, such increase is less than the linear prediction ( $LI < 1$ ). The interaction is therefore facilitatory but subadditive.

**$MI > 1, LI = 1$**  The interaction is linear ( $LI = 1$ ), which is an interesting regime because the model is nonlinear. Note that  $LI = 1$  implies  $MI > 1$  for non-negative responses.

**$MI > 1, LI > 1$**  The interaction is superadditive ( $LI > 1$ ). As discussed previously, such an effect is possible if both of the elements are at low contrast and their separation is sufficiently small. The two elements effectively merge into one. The response is therefore well-described by the contrast response function, which is expansive (superadditive) at low contrasts.

These six regimes are the only possible interactions based on  $MI$  and  $LI$ . They are mutually exclusive and therefore divide the three-dimensional feature space of the stimulus into six non-overlapping groups. To illustrate the model's predictions, Figure 6.5 plots the groupings for four example slices of the feature space, each with a different contrast for  $G_0$ . The plots are taken at the center of  $G_0$ . Although it is usually not the location with the maximal interaction effect, the center is a fixed reference point, whereas the location with maximal effect varies with the specific combination of stimulus features. In addition, in physiological studies, responses from neurons with receptive fields at the center of the element are the most robust. It is therefore useful to compare plots taken at the center with the results of physiological studies that measure activity from a small group of neurons.

When the contrast of  $G_0$  is small (5%, Figure 6.5a), the interaction is superadditive if the contrast of  $G_1$  is below 10% and within  $0.5^\circ$  of  $G_0$  (dark blue region). This group shrinks as contrast of  $G_0$  increases. Interestingly, as a transition from this regime to those with subadditive facilitation (green) and no interaction (orange), there is a small group for linear interaction (light blue). Similar to the superadditive group, this group also shrinks as the contrast of  $G_0$  increases. At low-to-medium  $G_0$  contrast (5-10%; Figures 6.5a and b), about one third of the interactions consist of subadditive facilitation. Such interaction is due to the weak normalization in the second stage of the model that prevents the interaction from being completely linear. When  $G_0$  is at high contrast ( $\geq 25\%$ ; Figures 6.5c and d), this group gets smaller and is replaced by winner-take-all interaction (red): the response to  $G_0$  dominates because  $G_1$  is either at a contrast that is too

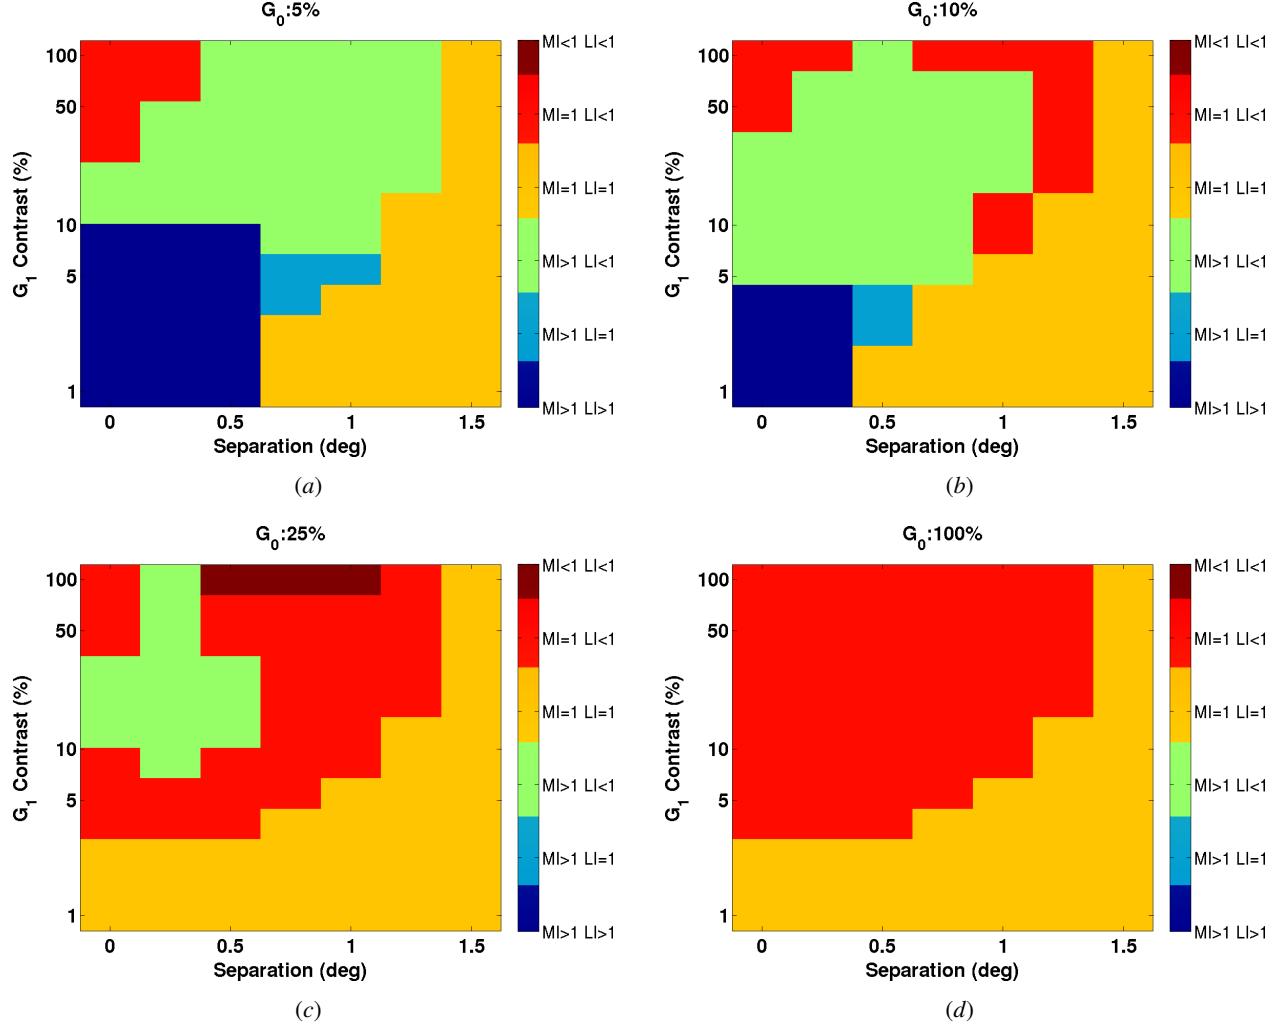

Figure 6.5: **Different regimes of the interactions at the center of  $G_0$ .** Each subfigure plots, for a particular  $G_0$  contrast, the regimes of interactions due to the different combinations of the  $G_1$  contrast and separation. When the contrast of  $G_0$  is less than or equal to 10% ((a)-(b)), the interaction ranges from superadditive to subadditive and is not suppressive. At higher  $G_0$  contrast, only subadditive regimes are possible. Suppression can also occur for certain combinations. When  $G_0$  is at 100%, there is either no interaction (because the separation is too large or the contrast of  $G_1$  is too low), or the response to  $G_0$  completely dominates the responses at the center. The model therefore predicts that the most changes of the regimes occur when the contrast of  $G_0$  is low. There is no interaction beyond  $1.5^\circ$  separation.

low or it is too far away from  $G_0$  to exert an affect at center location. When the contrast of  $G_1$  is 100%, its interaction with a 25% contrast  $G_0$  that is  $0.5^\circ$  to  $1^\circ$  away is suppressive. Despite the weak normalization in the second stage of the model,  $G_1$  located at such distances is strong enough to contribute heavily to the normalization activity at the center location without increasing the receptive summation significantly, thus reducing the response. Finally, for all contrasts of  $G_0$ , about a third to one half of the slices does not result in any interaction: Either the separation is too large or the contrast too low to have any effect on the response at the center location.

As can be seen in Figure 6.5 and the examples in the previous sections, the model predicts that the most interesting nonlinear interactions occur when  $G_1$  is at a higher contrast than  $G_0$ . The interactions

between the elements also depend on their separation. If it is too small, the elements overlap and merge into one unimodal stimulus. If it is too large, there will be no interaction at all. The model predicts that a separation of  $0.5^\circ$  to  $1^\circ$  is the range in which the strongest effect can be observed experimentally for the particular size of the elements and eccentricity simulated. For larger elements, this range will expand because the overlap is substantial even with large separations. In addition, as eccentricity increases, the cortical magnification factor decreases and a larger visual space is mapped to a particular cortical distance. As a result, the range of separations for observing the strongest effect will scale up accordingly.

Although these predictions seem straightforward, they provide specific guidelines for designing physiological experiments. Such guidelines are valuable because there is a very large number of combinations for the element contrasts and separation but only a few of these can be tested in a single experiment due to various constraints (e.g. the subject cannot take part in an experiment indefinitely, quality of signal from a recording site drops over time, etc). Having an estimation of the set of stimuli that is most likely to produce interesting and informative results is therefore important for designing experiments. In the next section, results of a VSDI experiment using the stimuli based on these guidelines are presented.

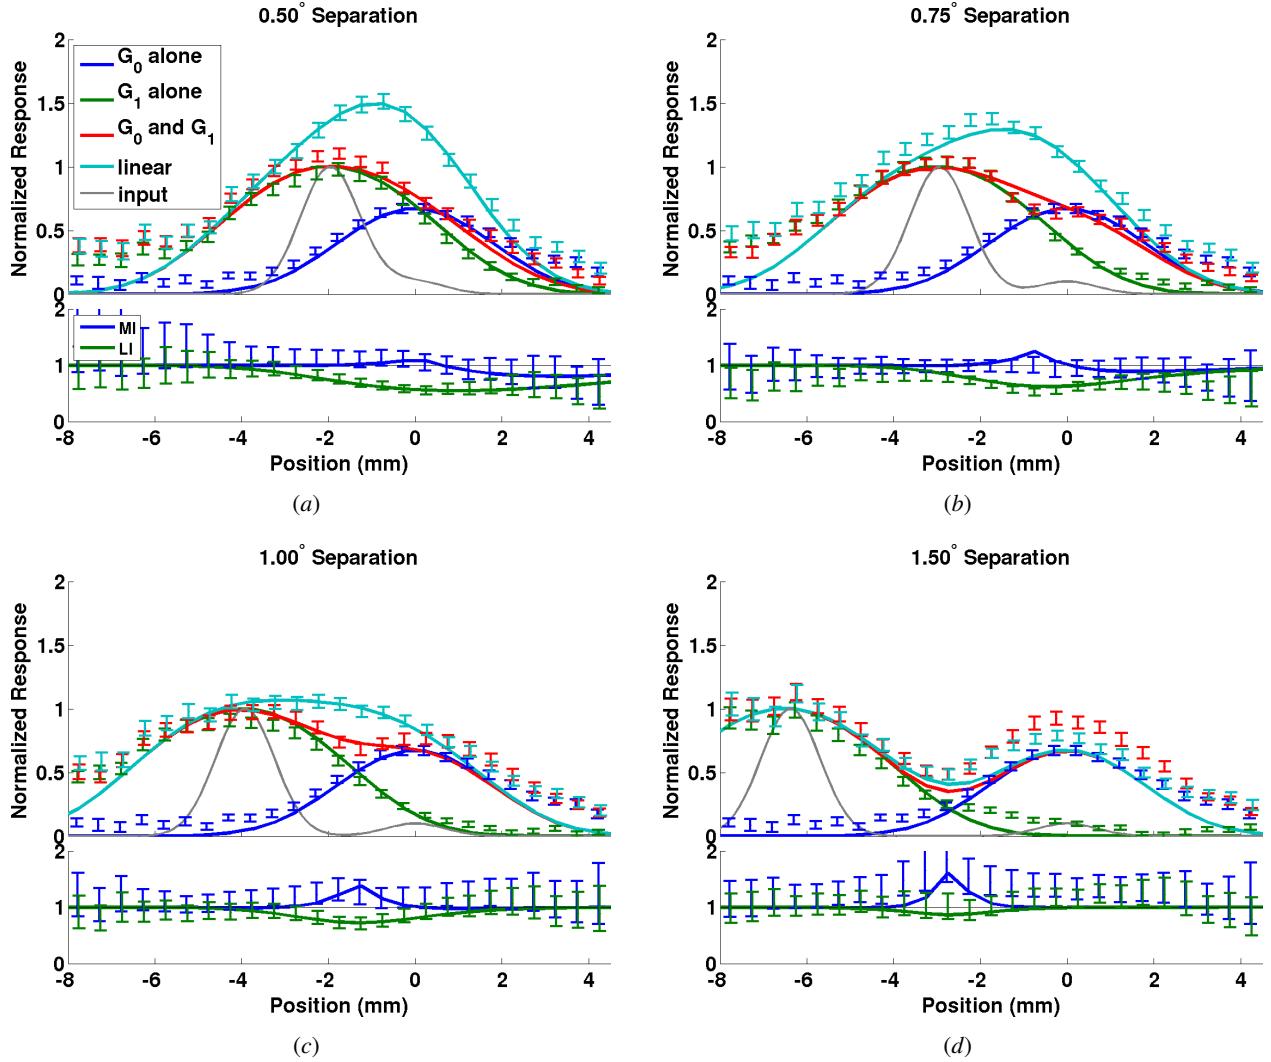

#### 6.2.4 Results of VSDI experiments

A set of VSDI experiments was carried out using the stimuli based on the guidelines from the model to study the interactions between two Gabor elements. The model's predictions were found to be largely consistent with the VSDI responses, suggesting that population gain control is a general mechanism for visual processing.

##### Experimental procedures and data analysis

The experiments were similar to the one described in Section 4.2.1. In each trial, the monkey only had to maintain his gaze at a fixation point while the stimulus was presented. As in the simulations, the element  $G_0$  was held fixed (at  $2.4^\circ$  eccentricity) and only the location of  $G_1$  would change. The orientations and the alignment of the two elements were vertical. Unlike in the previous experiment, the stimulus was presented for 50 ms and then disappeared for 150 ms, for 5 cycles (5 Hz). Such periodic stimuli provide a better signal-to-noise ratio in the VSDI responses than the briefly presented stimuli used in Chapter 4. These experiments were run by Bill Bosking.

The VSDI signals were processed by procedures that were similar to those described in Section 4.2.2. A 1.5 mm wide strip that passed through the centers of the responses for the two elements was considered. For each trial the VSDI signals were averaged across the width of the strip to collapse the signals into one dimension. After removing the average signal of the blank condition, the Fourier amplitudes of the time courses at the stimulus frequency (5 Hz) were extracted for each location and for each trial. The 5 Hz amplitude provided a much better signal-to-noise ratio than the peak response and the average response over a 100-ms time window; all the results presented in this section are therefore based on the 5 Hz component. Accordingly, the PGC model was simulated using such stimuli and the 5 Hz components of the responses were used to plot all the figures in this section. The 5 Hz component and the peak response of the model are similar.

**Figure 6.6: Spatial VSDI responses for stimuli consisting of a 10% contrast element and a 100% contrast element.** Each subfigure plots the spatial profiles and the *MI* and *LI* indices for a particular separation (thin curves). The response to the 10% element is centered at location 0. For this and the remaining figures in this chapter, error bars denote the 95% bootstrap confidence interval of the mean response at each location. The smooth curves are the predictions of the model from Figure 6.2. At most locations, the responses and the indices of the model fall within the confidence intervals. The model can therefore account for the interactions for such combinations of elements.

### Interaction of elements with different contrasts

The model predicts that the most interesting interactions occur when the contrasts of the two elements are very different. Based on this prediction, in this set of VSDI experiments,  $G_0$  was at 10% while  $G_1$  was at 100%. Four separations ( $0.5^\circ$ ,  $0.75^\circ$ ,  $1^\circ$ , and  $1.5^\circ$ ) were tested to understand how the interactions change with distance. The responses presented in this section are the average of two individual experiments.

Figure 6.6 plots the spatial profiles and the *MI* and *LI* indices of the VSDI responses for four different separations (thin curves). The error bar at each location denotes the 95% bootstrap confidence interval. The smooth curves are the predictions of the model using the same parameters as in the previous section. At most locations, the model's predictions for the responses, *MI*, and *LI*, lie within the 95% confidence intervals of

the VSDI responses, suggesting that the PGC model can account for the interactions.

Beyond -6 mm from the center, the VSDI responses change slowly across space and are larger than the model's prediction. The higher VSDI responses at these locations may be due to noise near the border of the VSDI image because the profiles of the responses to single elements should be symmetrical, as shown in Figure 4.2 and the prediction of the model (green curves; note that portions of them are covered by the red curves). On the other hand, these responses could be due to a spread of activity beyond the cortical point image that the model does not take into account. More experiments are required to determine whether the responses at these location are noise or stimulus-driven activity.

As predicted by the model, most of the VSDI responses to the two-element stimuli are smaller than the linear prediction. There is some weak suppression at the positive locations when the separation is  $0.5^\circ$  to  $0.75^\circ$  (Figures 6.6a and b), which is also consistent with the model's prediction (Figures 6.2b and c).

Importantly, as predicted by the model, the location of the largest effect of interaction, i.e. the peak or trough of *MI* and *LI*, is usually not at the center of the elements. Instead, it is in the middle between the two elements. This result illustrates the importance of measuring the responses over a large region and how insight about the interactions can be gained from computational models.

When the separation is  $1.5^\circ$  (Figure 6.6d), the VSDI responses around the center of  $G_0$  are enhanced and the interaction is superadditive. An inspection of the response time courses showed that the enhancement is not due to an increase in peak amplitude, but due to the larger drop in the falling edge which increases the modulation depth and hence the 5 Hz component of the response. Such effect may be due to orientation-specific suppression that is mediated through long-range, slow intracortical lateral connections or intercortical feedback connections, or both. If further experiments verify that there is indeed a larger drop in the falling edge, the PGC model needs to be extended to take the orientation-specific signals into account. Chapter 8 discusses how these signals can be incorporated into the PGC model.

## Interaction of high-contrast elements

When the contrasts of both elements are high, the model predicts that the interactions will be mostly sub-additive and winner-take-all for all locations except those in the middle between the elements where some facilitation can occur (Figure 6.3). In one VSDI experiment, the interactions between two 25% contrast elements were studied. Figure 6.7 plots the spatial profiles and the corresponding *MI* and *LI* indices for the four different separations tested in this experiment. Consistent with the model's predictions, the profile of the responses for the two-element stimuli is essentially the maximum of the responses for the individual elements, with some facilitation in the middle between the elements. The model also provides a good fit to the *MI* and *LI* indices.

There is very little interaction between the elements for such combination of contrasts, as predicted by the model. Most of the responses are not affected by  $G_1$ . These stimuli therefore are not very useful for understanding the interactions. This result illustrates the importance and difficulty of stimuli selection in experimental design. In fact, this experiment was carried out before the PGC model was applied to such stimuli. At that time there was no information about which combinations would provide the most interesting interactions. Models that can predict neural responses accurately, such as the PGC model, are therefore valuable tools to guide new experiments.

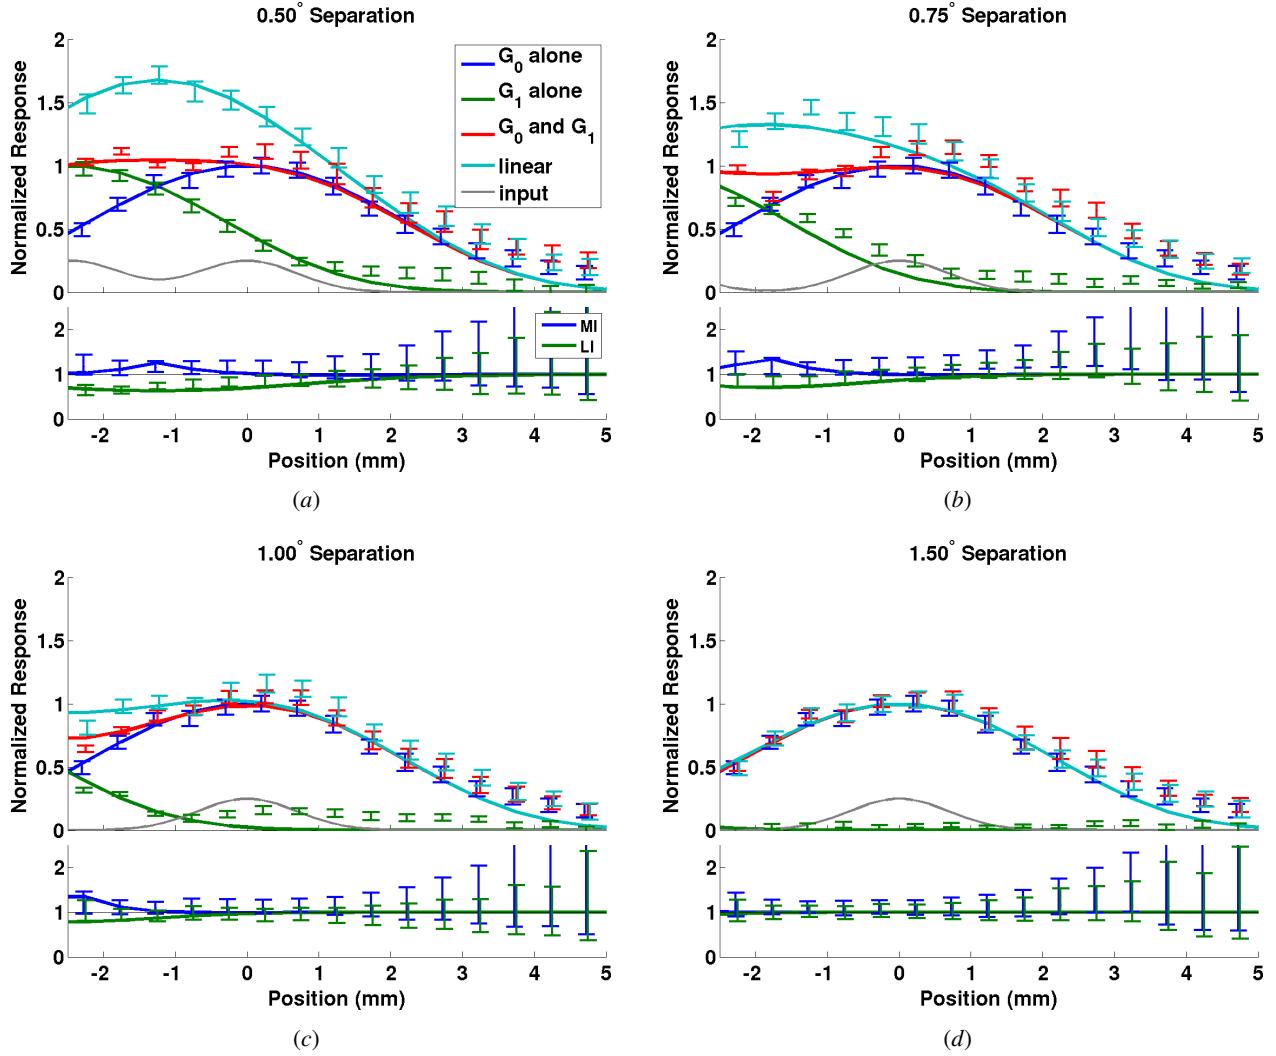

Figure 6.7: **Spatial VSDI responses for stimuli consisting of elements at 25% contrast.** In this experiment, the responses at the  $G_1$  locations fell outside of the recording chamber and were not recorded. However, due to symmetry, it can be concluded that there is little interaction between the two elements. The model’s predictions (smooth curves) resemble the VSDI responses and the indices (error bars) and hence are consistent with the data.

### Interaction of low-contrast elements with fixed separation

When both of the elements are at low to medium contrast, the model predicts that the interaction at the center is mainly facilitatory ( $MI > 1$ ) when the separation between the elements is about  $0.75^\circ$  (Figures 6.5a and 6.5b). Specifically, when both of the elements are at 5% contrast, the interactions at all the locations are linear ( $LI = 1$ ), with the most facilitation in the middle between the elements (Figure 6.4c). When the contrast of both elements increases to 10%, the interaction at the center becomes subadditive ( $LI < 1$ ) while remaining facilitatory (Figure 6.5b).

To test these predictions, the VSDI responses to stimuli consisting of elements at the same contrast separated by  $0.75^\circ$  were measured. Figures 6.8a and 6.8b plot the spatial profiles and the corresponding  $MI$  and  $LI$  of the VSDI responses for the stimuli at 5% and 10% contrast, respectively. Consistently with the

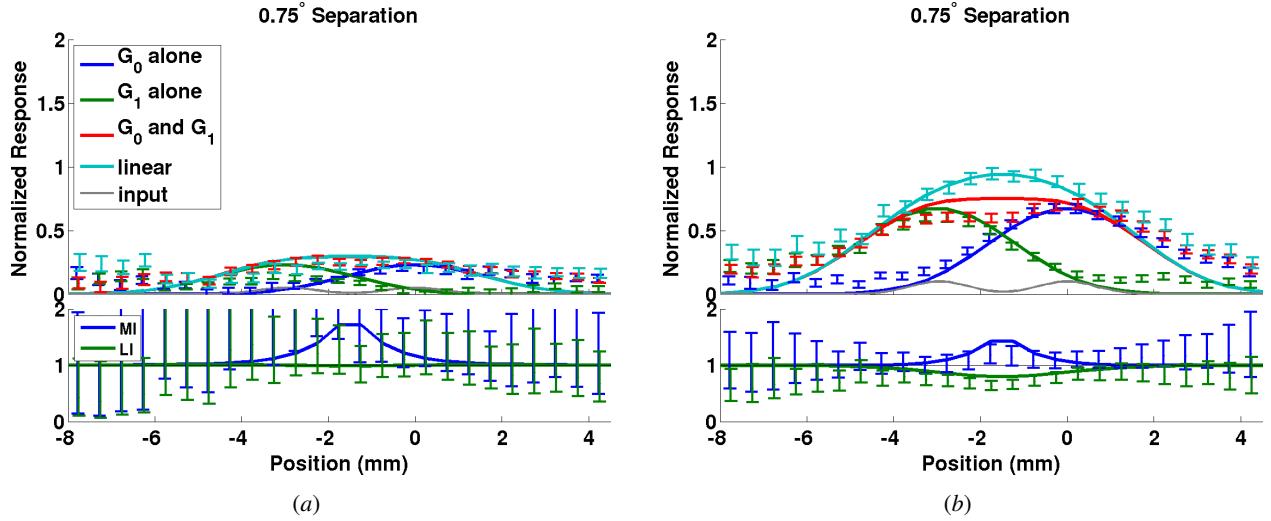

Figure 6.8: **Spatial VSDI responses for stimuli consisting of elements at low to medium contrasts with  $0.75^\circ$  separation.** (a) Both elements are at 5% contrast. The responses are very weak and noisy, yet they are quite similar to the model's predictions (thick smooth curves). (b) Both elements are at 10% contrast. The interaction mainly follows a winner-take-all rule. The model's prediction is higher than the VSDI responses in the middle between the elements, but the predicted *MI* and *LI* are still within the confidence intervals, suggesting the model provides a reasonable fit to the data.

model, for 5% stimuli, *LI* is close to 1 across different locations, while *MI* increases in the middle between the elements (Figure 6.8a). At the locations around  $G_1$  (-3mm), the measured *MI* remains large, which is probably due to the the low signal at these locations: The amplitude of the response at the center of  $G_1$ , when it is presented alone, should be the same as that for  $G_0$  at its center, but the measured response for  $G_1$  was lower than expected.

When both of the elements are at 10% contrast, the model predicts *MI* to be larger than 1 and *LI* to be less than 1, which is consistent with the VSDI responses (Figure 6.8). Note also that the peak of *MI* and trough of *LI* are not at the center of either element.

In summary, the PGC model can account for most of the interactions observed in the VSDI responses for a large range of stimulus configurations. This result suggests that the PGC model provides a good approximation to the processing in the visual cortex for spatial interactions of the elements.

### 6.3 Center-surround interactions

In addition to stimuli containing two small elements, interesting interactions may be observed when a small element is embedded in a large non-uniform background. In this section, the effect of a large Gabor background on a small Gabor element with the same orientation, phase, and spatial frequency is explored using the model. Figure 6.9 shows three example stimuli with different background contrasts and a fixed center element. As can be seen in these examples, the detectability of the small element depends on the background contrast. Interestingly, psychophysical and physiological studies using similar stimuli have shown that the background does not always decrease the detectability or response for the small element; facilitation can occur for some combinations of element and background contrasts (Ejima & Takahashi, 1985; Cannon & Fullenkamp, 1993; Levitt & Lund, 1997). Using the same approach in analyzing the interactions between

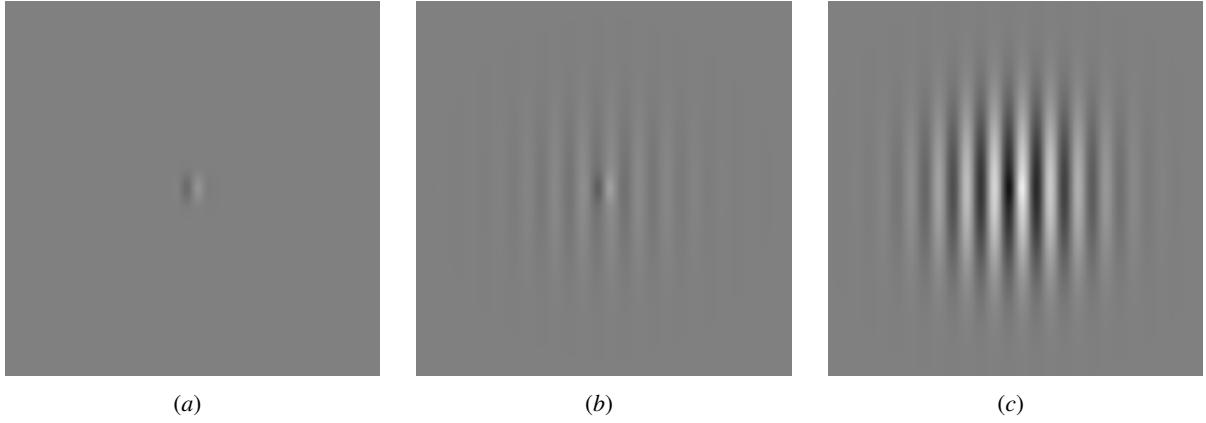

Figure 6.9: **Example center-surround stimuli.** The center element has a contrast of 40% in all subfigures. The contrasts of the background Gabor are 0%, 10%, and 60% for (a), (b), and (c), respectively. Even though the center element is at a fixed contrast, its visibility in these figures is very different, suggesting significant interactions from the background.

two elements, the PGC model is used to predict the responses for all combinations of contrasts.

For the model, the input consists of a small Gaussian element  $G_0(x)$  that is on top of a concentric Gaussian background  $G_1(x)$ . Using the same notations in Section 6.2.1, the activity of the input layer during the stimulus presentation is

$$V_{in}(x) = \min(G_0(x) + G_1(x), 1) \quad (6.3)$$

$$= \min(c_0 G(0, \sigma_0) + c_1 G(0, \sigma_1), 1). \quad (6.4)$$

The width  $\sigma_0$  of the center element  $G_0$  was chosen to be the same as in the previous simulations and in the VSDI experiments, which is  $0.167^\circ$  in visual space. The width of the background was six times as large ( $1^\circ$ ) to cover a large space. The magnitudes of the center and the background were varied independently. The PGC model was simulated using the same parameters as in the previous section.

### 6.3.1 Predictions of the model on the responses at stimulus center

As in the characterization of the responses for the two-element stimuli, the center-surround interactions at the stimulus center for different contrast combinations can be characterized by plotting the groupings of the different regimes (Figure 6.10). When the contrasts of both the small element and the background are low, the response at the center is enhanced, and when the contrasts are high, there will be suppression. The transition from superadditive facilitation to suppression is systematic. Except for very low contrasts, as either one of the contrasts increases, the facilitation weakens, which eventually leads to suppression when both contrasts are high.

Such systematic decrease in facilitation can be understood by a qualitative analysis of the model's responses. First, consider the case where the contrast of the background is fixed. The background therefore has constant contributions to the receptive field summation and the normalization activity at location 0. As an approximation, the background can be treated as an element that has the same size as  $G_0$  for this location. This element thus completely overlaps with  $G_0$  and they can be considered as one single element. The weakening of facilitation as the contrast of  $G_0$  increases can then be explained by the sigmoidal shape

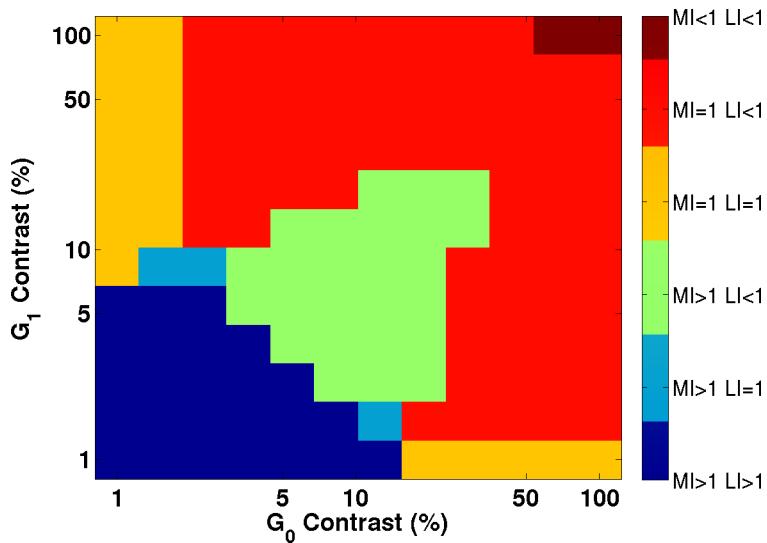

Figure 6.10: **Different regimes of interactions when the contrasts of the elements are varied.** There is a clear systematic change of the interaction as the contrast of the elements increases, demonstrating the advantage of characterizing the interactions over the entire feature space using the model.

of the contrast response function (Figure 5.3). The same argument applies when the contrast of the  $G_0$  is fixed while the background contrast increases.

While the prediction of the systematic decrease in facilitation may not seem surprising, it is very specific and can be tested in physiological experiments. A particularly interesting experiment will be testing the stimuli along the diagonal in Figure 6.10 where the contrasts of the small element and the background are equal. The model predicts that the  $LI$  index will decrease as the contrast increases. One advantage of using such stimuli experimentally is that only one feature of the stimulus, i.e. the common contrast, has to vary instead of two. The number of conditions required is therefore greatly reduced, demonstrating how the model can provide valuable guidelines for designing experiments.

## 6.4 Behavioral predictions

One of the most interesting and important questions about the stimuli studied in this chapter is how the visibility, or detectability, of an element is affected by a nearby or surrounding element. Psychophysical experiments using similar stimuli have shown that the detection threshold of an element is indeed affected by the surrounding elements (Ejima & Takahashi, 1985; Cannon & Fullenkamp, 1993; Polat & Sagi, 1993). Assuming that the observer's detection of the element is based on the responses in V1, different hypotheses concerning how neural responses are decoded to give rise to perception can be tested on such stimuli using the responses from the PGC model.

In this section, a simple decoder that compares the responses integrated over a time window to a fixed threshold is studied. Based on the starting time of the integration window, the predicted detection threshold can be surprisingly different, illustrating that interesting insight can be gained through the model.

### 6.4.1 A simple decoder

One simple way to decode neural responses is to integrate the response over a fixed time window (after removing some background activity), and then compare the integrated response to a fixed threshold (Gold & Shadlen, 2001, 2002; Mazurek, Roitman, Ditterich, & Shadlen, 2003). If it is above the threshold, then the output of the decoder will be positive (“element detected”), and vice versa. This simple decoder can be used with the VSDI responses because the noise in the signal is additive and independent of the stimulus (Y. Chen et al., 2008). The underlying stimulus-driven signals in the responses can therefore be estimated by a simple temporal integration.

For simplicity, only the response at the center of  $G_0$ , i.e. location 0 in the modeled region, is considered in this section. In other words, the output of the decoder is positive if

$$\int_{t_0}^{t_1} V(0, t) - V_b(0, t) dt \geq V_{th}, \quad (6.5)$$

where  $t_0$  and  $t_1$  are the start and end time of the integration time window, respectively.  $V(0, t)$  is the response at location 0,  $V_b(0, t)$  is the baseline activity at location 0 that has to be removed, and  $V_{th}$  is the threshold. The result of the integration is called the residue.

For the stimuli used in this chapter, the baseline activity that needs to be removed is the response due to  $G_1$  at location 0 when it is presented alone. This removal assumes the subject has a memory of the responses to  $G_1$  by itself, which is possible in experimental settings where the observers are usually well trained.

The threshold  $V_{th}$  is assumed to be the integrated response over the same window used in the decoder for a 3% contrast  $G_0$  over a uniform background. Such benchmark contrast is similar to the detection threshold of the monkeys used in the VSDI experiments for the single input elements.

The output of the decoder has an interesting relationship with the *LI* index when responses are integrated at their steady states. In this case, the output of the decoder is positive when

$$V_s(0) - V_{bs}(0) \geq V_{th_s} \quad (6.6)$$

$$\frac{V_s(0)}{V_{th_s}(0) + V_{bs}(0)} \geq 1, \quad (6.7)$$

where the subscript s denotes steady state responses. Note that  $V_b(0)$  is the response when both elements are present and  $V_{bs}(0)$  is the response when  $G_1$  is presented alone. If  $G_0$  is at 3% contrast,  $V_{th_s}(0)$  is also the response for  $G_0$  alone and the above inequality becomes  $LI \geq 1$ . As a result, a 3% contrast  $G_0$  is detectable by the decoder for a given  $G_1$  if the *LI* for that combination is larger than or equal to 1. Consequently, if *LI* is strictly larger than 1, the detection threshold will be lower than 3% because the contrast of  $G_0$  can be reduced such that  $V_s(0)/(V_{th_s}(0) + V_{bs}(0)) = 1$ .

As it turns out, the output of such a simple decoder can be very different when a different time window is used. The effect for both two-element and center-surround stimuli will be discussed next.

### 6.4.2 Two-element stimuli

Two different 100 ms time windows were used in the decoder. The first one starts 50 ms after stimulus onset, and the second one starts at 150 ms. To study how the detection threshold is affected by another element, for each separation, the residue was computed for different combinations of  $G_0$  and  $G_1$  contrasts.

Figures 6.11a-d plot, for four example separations, the residues as a function of  $G_0$  contrast for different  $G_1$  contrast (0% means  $G_1$  is absent). The dashed line plots the threshold that corresponds to the detection of  $G_0$  at 3% contrast on a uniform background. The output of the decoder will therefore be positive when the curve is above the dashed line. The detection threshold for a particular  $G_1$  contrast at a particular separation can therefore be read off from the  $G_0$  contrast at the crossover point between the corresponding curve and the dashed line.

When the two elements completely overlap ( $0^\circ$  separation, Figure 6.11a), the detection threshold is reduced significantly as the contrast of  $G_1$  increases from 0% to 5%. The threshold is less than 0.5% even when  $G_1$  is at 10%, which is a large effect and has not been observed experimentally. The reduction of threshold is partially due to the expansive contrast response function at low contrasts. As the contrasts of the  $G_1$  increases, the slope of the contrast response function decreases. A higher  $G_0$  contrast is therefore required to increase the residue to overcome the threshold. As a result, the predicted detection threshold increases. When  $G_1$  is at 50% contrast, the responses saturate and the overlapping  $G_0$  becomes undetectable. As the separation between the elements increases, the interactions and hence their effects on detection threshold decrease rapidly (Figures 6.11b-d). The prediction of this decoder over a large range of  $G_1$  contrast and separation combinations is plotted in Figure 6.11e.

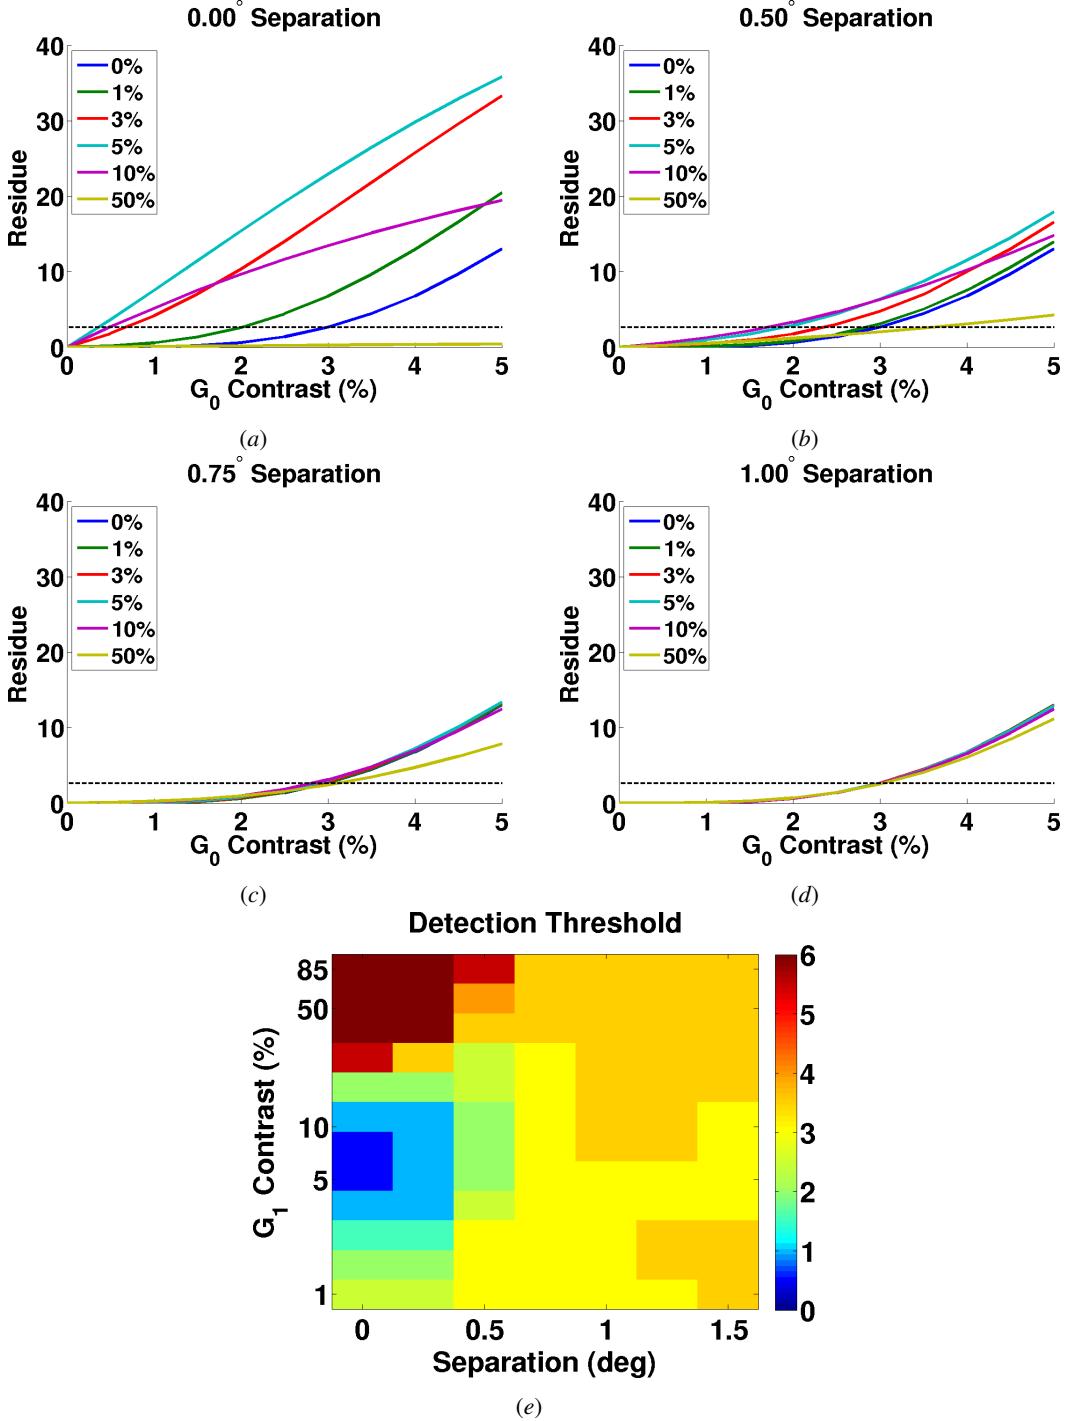

When the second integration window (150-250 ms after stimulus onset) is used, the behavior of decoder changes (Figure 6.12). When the two elements overlap and the contrast of  $G_1$  is below 5%, the reduction in threshold is less than that of the first decoder (Figure 6.12a). The most dramatic change is for higher  $G_1$  contrast. At 10%, the detection threshold for  $G_0$  becomes 3%, whereas it is 0.5% in the first decoder. There is also a larger increase in detection threshold for high  $G_1$  contrast and at wider separation.

Such a change in behavior can be understood through the time courses of the responses. Figure 6.13a plots the time courses of (1) the responses to a 1.5% contrast  $G_0$  overlapping with a  $G_1$  at 10% contrast, (2) the response to  $G_1$  alone, (3) their difference (residue), and (4) the response to the 3% contrast  $G_0$  that serves as the threshold. Due to the difference in the rising edge slopes at different contrasts (Figure 5.3), the residue increases rapidly after response onset and is larger than the response to the 3% contrast  $G_0$  until about 150 ms. As a result, if the integration window is within this time span, the output of the decoder will be positive and the 1.5% contrast  $G_0$  will be “detected”. After that time, the residue becomes smaller than the response to the 3% contrast  $G_0$  and remains so when the response drops after stimulus offset. As a result, if the integration window is after 150 ms, the 1.5% contrast  $G_0$  will be “invisible”. The detection threshold therefore changes from below 1.5% to above that when a later window is used.

Figures 6.13b-d plot the spatial profiles of the responses to these stimuli and the residue at different time points after stimulus onset. Early on during stimulus presentation, the residue is larger than the response to the 3% contrast  $G_0$  at all locations (Figure 6.13b). As time progresses, this response rises and is similar to the residue at the center location, which finally becomes larger than the residue, as described before (Figures 6.13c and d). On the other hand, at the periphery, the residue can be larger than the response to the 3% contrast  $G_0$  at all these time points, suggesting that the responses at these locations may contain useful information for detection.

### 6.4.3 Center-surround stimuli

The two decoders were applied to the center-surround stimuli using the predicted responses of the PGC model. As can be seen in Figures 6.14 and 6.15, the difference between the two decoders is similar to that for the two-element stimuli, but more dramatic. With the first decoder, the detection threshold is reduced,

**Figure 6.11: Detection threshold under different stimulus configurations using an integration window of 50-150 ms after stimulus onset.** (a)-(d): The residue as a function of  $G_0$  contrast for four example separations. Each curve plots the residue when  $G_1$  is at the labelled contrast. The dashed line shows the threshold, which is the residue of a 3% contrast  $G_0$  on a uniform background, i.e. value of the blue curve at 3% contrast in the figures. The  $G_0$  contrast at which a curve crosses over the dashed line is the detection threshold for that stimulus configuration. The largest change in threshold occurs when the separation is small. (e) Detection thresholds for different combinations of  $G_1$  contrast and separation. If the threshold is below the 3% benchmark, the threshold is reduced through the interaction with  $G_1$ , and vice versa. Note that the threshold is actually much larger than 6% when  $G_1$  has a contrast above 50% at a separation that is less than 0.5°, even though this is not visible using the color scale above.

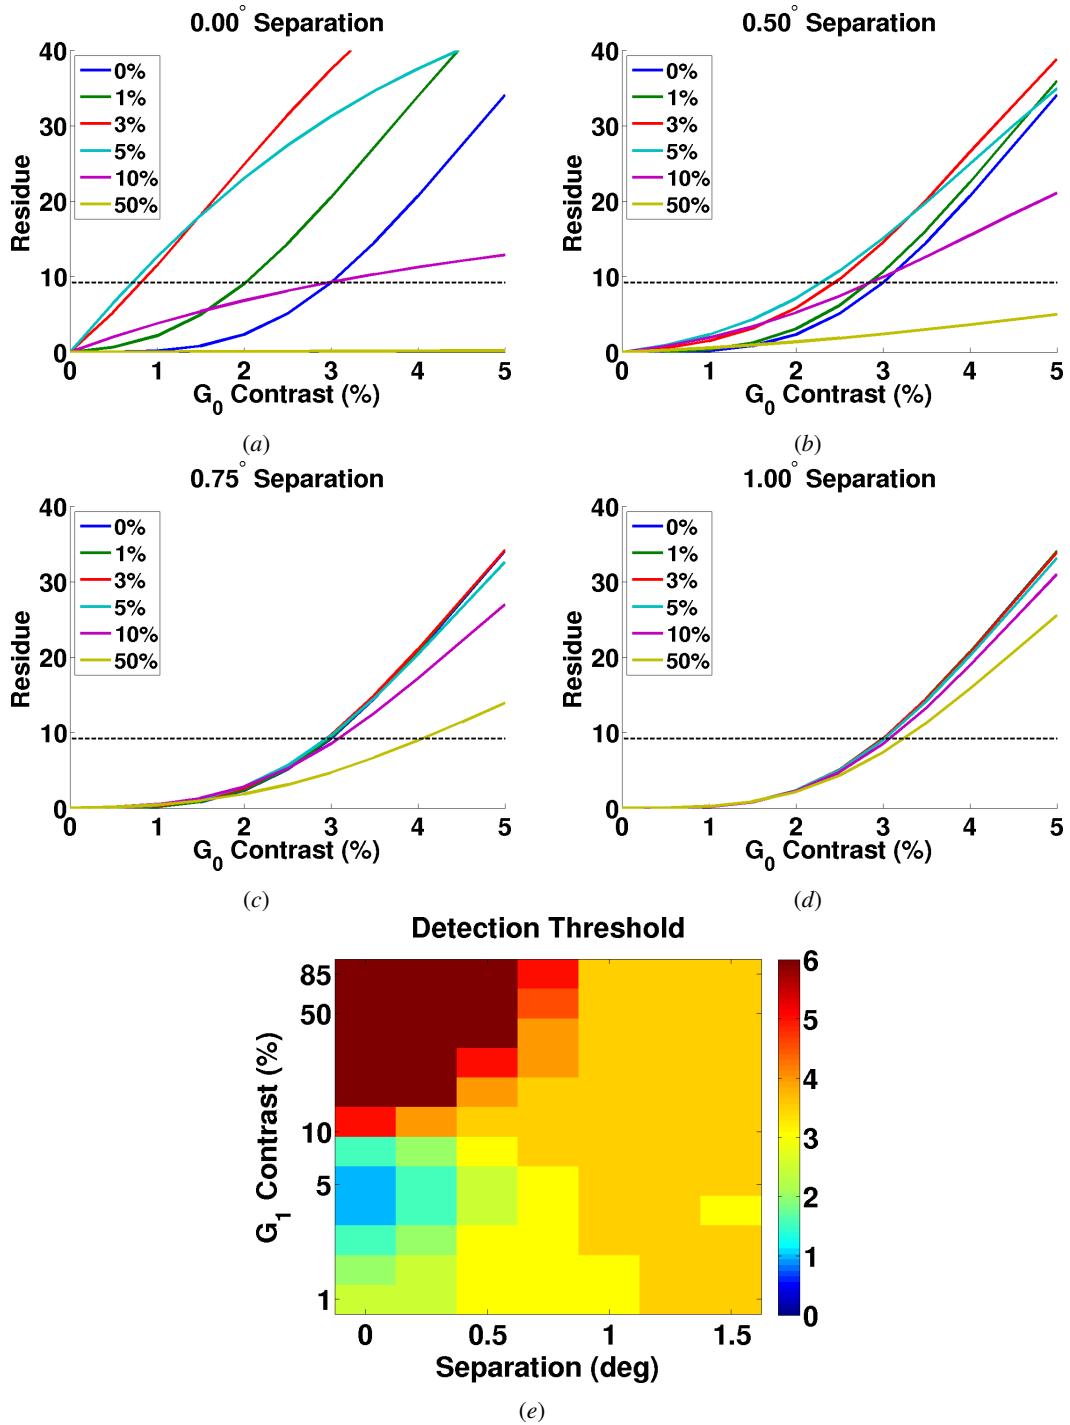

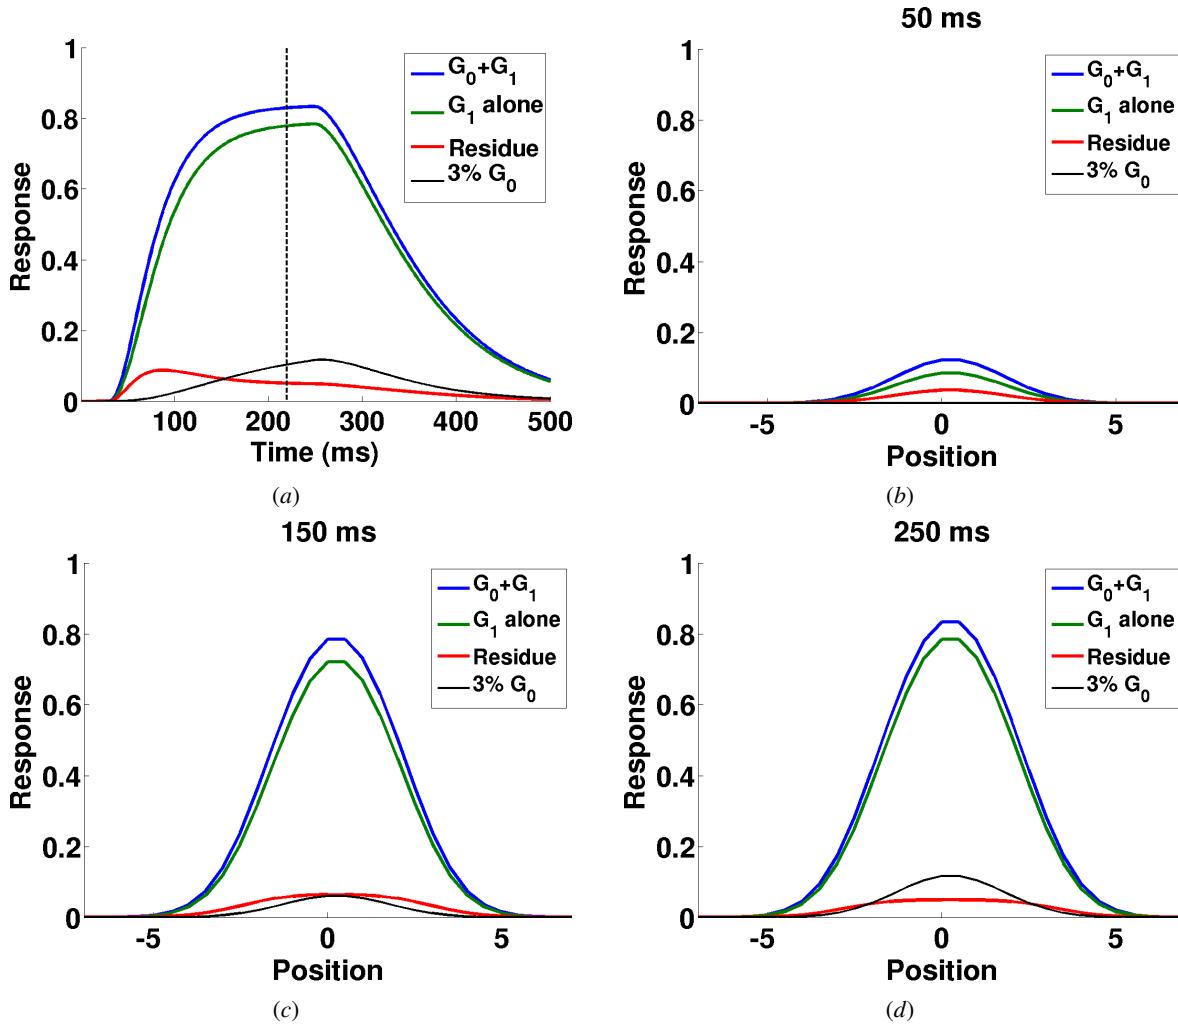

Figure 6.12: **Detection threshold using an integration window of 150-250 ms after stimulus onset.** The reduction in threshold is less than that with an earlier window. There is also a large increase in threshold when the contrast of  $G_1$  is beyond 10%. The integration window therefore affects the detection threshold in two-element stimuli.

**Figure 6.13: Time course and spatial profiles at different time points for an example configuration of stimuli.** (a) Time courses of the center responses to the stimuli containing both overlapping elements (blue),  $G_1$  only (green), and the difference between them (residue; red). The contrasts of  $G_0$  and  $G_1$  are 1.5% and 10%, respectively. The response to the benchmark (3% contrast  $G_0$ ; black) is also plotted. The stimulus was presented from 0 to 220 ms (vertical dashed line) and disappeared after that, and the responses started to drop at about 250 ms. (b)-(d) Spatial profiles of the responses and the residue at 3 different time points. The relationship between the residues and the benchmark changes over time, which explains why the thresholds are usually higher when the integration window starts late.

i.e. below 3%, up to a  $G_1$  contrast of about 12% (Figure 6.14b). The reduction in threshold for the second decoder is smaller and only occurs when the contrast of  $G_1$  is below 5%. Beyond that, the threshold increases very rapidly (Figure 6.15b).

#### 6.4.4 Proposed psychophysical experiments with VSDI

Because the predicted detection threshold is more sensitive to the integration window for the center-surround stimuli, they should be used instead of the two-element stimuli in psychophysical experiments to study how the interactions affect perception and how population responses in V1 should be read out by higher level

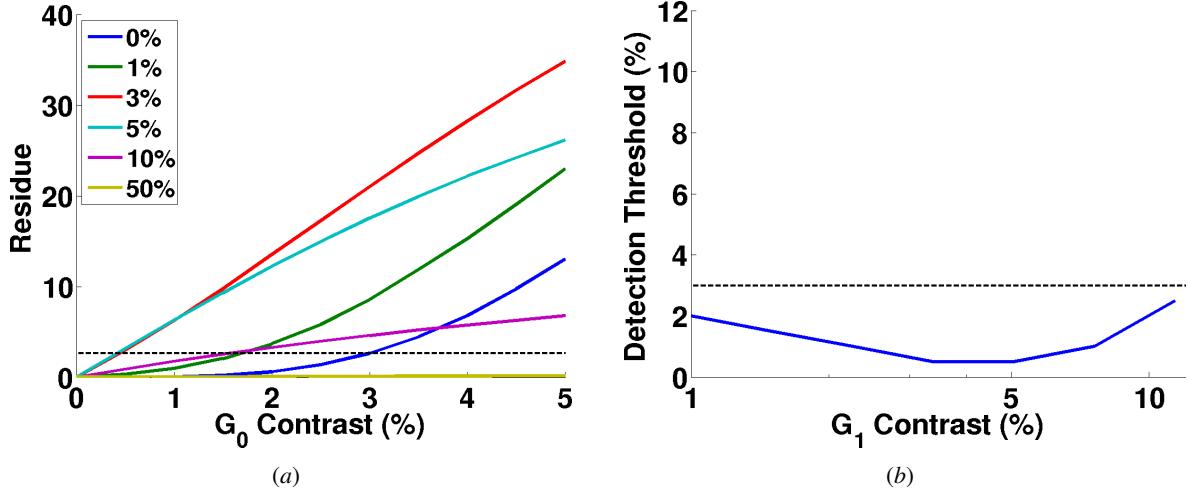

Figure 6.14: **Detection threshold using an integration window of 50-150 ms after stimulus onset for the center-surround stimulus.** (a) The residue as a function of  $G_0$  contrast for different background contrasts. (b) Detection threshold as a function background contrast. The dashed line plots the benchmark threshold of 3% contrast. There is a reduction in threshold even with medium background contrast.

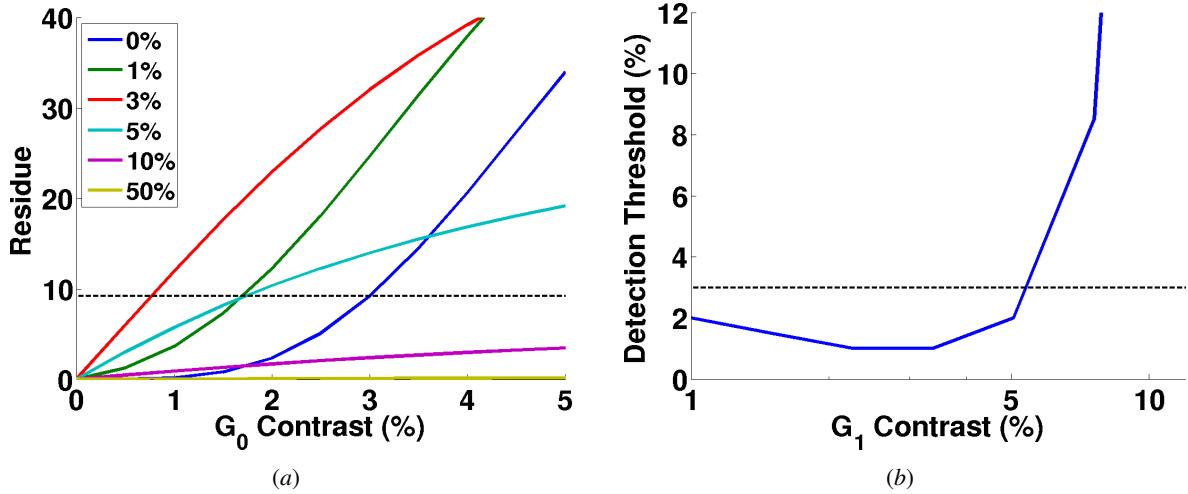

Figure 6.15: **Detection threshold using an integration window of 150-250 ms after stimulus onset for the center-surround stimulus.** (a) The residue as a function of  $G_0$  contrast for different background contrasts. (b) The detection threshold increases dramatically when the background contrast is higher than 5%, which is different from the prediction using an earlier integration window, suggesting that the timing of the window affects the threshold significantly for center-surround stimuli.

areas. A simple reaction-time visual detection task with simultaneous VSDI recording that is similar to the experiment described in Y. Chen et al. (2006, 2008) can be used for such a study. In each trial, after the monkey establishes fixation, the stimulus appears briefly, e.g. 300 ms, at a fixed location. In the center-present trials, the monkey has to shift gaze to the center element of the stimulus within a short time period, e.g. 600 ms, after stimulus onset to get the reward. For center-absent trials, the monkey has to remain fixated for an additional time period, e.g. 1 s, after stimulus offset to obtain the reward. In a block of experiment, the surround element is at the fixed contrast, while several, e.g. 5, different contrast levels that span the

monkey's detection threshold are tested for the center element. The numbers of center-present and center-absent trials in each block are the same and the different conditions are interleaved pseudorandomly. The VSDI responses are recorded while the monkey is performing the task. Using these measured responses, an optimal Bayesian decoder for the task can be found to show how the responses should be read out to achieve best performance, which could provide insight on how the responses are used in the monkey's visual system by comparing the performance between the monkey and the decoder (Y. Chen et al., 2006, 2008).

#### 6.4.5 Summary

Using a simple decoder that integrates the response and compares it with a predefined fixed level, an interesting relationship between the detection threshold and the integration time window was found for the two-element and center-surround stimuli. An early integration window results in a larger reduction in detection threshold, which is desirable in most cases. If the integration starts later, the threshold is reduced less. Based on this prediction, psychological and physiological experiments can be designed to shed light on how the neural responses in the primary visual cortex are used in the downstream areas. This result also demonstrates how new insight about perception can be gained from the PGC model.

### 6.5 Conclusion

While a single Gabor element on a uniform background is a widely used stimulus for characterizing the responses in the visual cortex, it is very different from natural scenes that contain more variation in local contrast. As the first step towards understanding visual processing in a natural setting, the PGC model was applied to two classes of stimuli that are more complicated.

The first class of stimuli contained two Gabor elements at various contrasts and separations. The model predicted that the interactions are mainly subadditive. At the center of an element, the interaction was predicted to vary the most when it is at low contrast. These predictions were used to design the set of stimuli in the VSDI experiments. Without the model's prediction, it would be difficult to estimate which feature combinations will produce the most interesting behavior. The model is therefore a useful tool for designing experiments.

The measured spatial VSDI responses turn out to be similar to the responses of the model over a large range of stimuli. Specifically, the model predicted that the largest effect of interactions usually occur at locations between the two elements, which is consistent with most of the data. This result illustrates the importance of modeling the whole spatial region instead of just a single point on the cortex. The PGC model can therefore account for most of the interactions observed in the VSDI responses for a large range of stimulus configurations, suggesting that the PGC model provides a good approximation to the processing in the visual cortex for spatial interactions of the elements.

The second class of stimuli consisted of a small Gabor element on top of a large Gabor background. The model predicted a systematic change in the linearity of the interactions as the contrasts of the two Gabors were varied. A specific physiological experiment was proposed to verify the prediction. This result demonstrates one key advantage of computational models: It can sample many different features of the stimulus to discover systematic changes.

The responses of the PGC model for these two classes of stimuli were also used to predict the interactions' effects on perception. Detection threshold of an observer for a particular stimulus configuration is predicted to be highly dependent on the timing of a simple decoder. This result demonstrates that the PGC

model can also be used to gain insight on how the high-level areas may use the information available in the V1 responses.

This chapter studied the spatial interactions of stationary stimuli and showed that the model's predictions are consistent with the VSDI responses. In the next chapter, non-stationary stimuli will be used to validate the model.

# Chapter 7

## Spatiotemporal Interactions Between Visual Stimuli

Even though the PGC model was motivated by the responses to a single Gabor stimulus, it can account for the responses to more general stimuli that consist of two stationary elements with various combinations of contrasts and separation, as was shown in Chapter 6. To test the generality of the model even further, non-stationary visual stimuli with moving contrast envelopes are used in this chapter. The predictions of the model were again found to be consistent with VSDI responses, suggesting that PGC is a general, accurate, yet simple model for population responses in the visual cortex.

### 7.1 Motivation

In the previous chapter, the PGC model was shown to account for the spatial interaction between two Gabor elements with a wide range of combinations of contrasts and separation. These two-element stimuli were stationary, however. A more challenging test for the generality of the model is to use non-stationary stimuli, i.e. stimuli that move around, and verify the predictions with the population responses in V1. This chapter reports such a verification using movies that contain a rotating wedge.

In the remaining of the chapter, the stimuli used will first be described, followed by the predictions of the model and the results of the VSDI experiment using such stimuli.

### 7.2 Spatiotemporal stimuli

The non-stationary stimuli studied in this chapter consist of a full-contrast wedge that is 5 angular degrees wide and rotates about the fixation point like a clock hand (Figure 7.1). Such stimuli were used in a previous study to obtain a precise retinotopic map of V1 with VSDI (Yang et al., 2007). Possible extensions of the model to account for the processing of spatiotemporal stimuli that contain motion within a stationary contrast envelope, e.g. drifting gratings, will be discussed in Section 8.2.1.

In the full counterclockwise stimulus (CCW movie; Figure 7.1), the wedge first appeared at 45 angular degrees off the vertical meridian ( $225^\circ$ ). At each 20 ms, the wedge rotated 5 degrees counterclockwise, until it reached 15 degrees on the other side of the visual field ( $285^\circ$ ). After that, the wedge returned to its starting position and the whole sequence repeated. A single sweep of the wedge therefore spanned 60

angular degrees and took 240 ms to complete. Although it is an artificial stimulus, it represents a common situation in which a moving object appears from behind an occluder and then disappears behind another occluder, e.g. a bird flying across a window. Figure 7.1 shows the stimulus at different times within a cycle.

In addition to the full movie, there was a cut movie where the wedge was only presented between  $240^\circ$  and  $270^\circ$  (CCW cut movie; Figure 7.1). The wedge therefore stopped at the vertical meridian and did not appear in the right visual field. The presentation time of each wedge with respect to stimulus onset was the same as in the full movie. In other words, the wedge only appeared during the middle 120 ms of the cycle, and the rest of the frames only contained the uniform background (Figure 7.1). The response for the first wedge in the cut movie ( $240^\circ$ ) can therefore be compared with the response at the same location when the full movie is underway to study the spatiotemporal interactions from previous wedges. If these responses are not the same, it implies that the perceived motion at the beginning and in the middle of the wedge's rotation may be different. Similarly, the response dynamics at the vertical meridian for the two movies can be compared to investigate whether the wedges in one hemifield (after the wedge in the full movie passes  $270^\circ$ ) will affect the responses in the other hemifield.

There were also three extra conditions in which only one wedge in the movie was presented. Again, the timing of the wedge presentation was exactly the same as in the full movie; the wedge was presented for 20 ms and the rest of the frames were blank in each cycle. Three wedge locations,  $240^\circ$ ,  $255^\circ$ , and  $270^\circ$ , were used in the VSDI experiments (Figure 7.1). Note that these wedges were presented at different times within the cycle. The responses for these single-wedge stimuli at their respective locations served as a baseline against which the responses for the movies were compared.

A set of clockwise (CW) stimuli that rotated from  $285^\circ$  to  $225^\circ$  were also used in a VSDI experiment (Figure 7.2). This set only contained the full movie and the cut movie and not the single-wedge stimuli. The response at the location where the cut movie ends can be compared with that for the full movie to study the effects of interactions from new, continuing wedges.

## 7.3 Results of the model

In this section, the representations of the stimuli in the input layer of the model will be described. The model's behavior with these stimuli will then be analyzed, followed by simulation results.

### 7.3.1 Input to the model

The stimuli described above have two interesting properties that simplify their representation in the model. First, because of the nonlinear retinotopic mapping in the macaque, the wedges are mapped to approximately parallel bands on V1. Figure 7.3 shows how the borders of the full movie stimulus in the left visual field are mapped to V1 in the right (contralateral) hemisphere. The border at  $225^\circ$  is mapped to a line that is posterior to V1 and is horizontal in the figure. As the wedge rotates counterclockwise, its mapping on the brain shifts in the anterior direction; the  $270^\circ$  wedge is mapped along the V1/V2 border that represents the vertical meridian.

Although the width of the wedge increases with eccentricity, the thickness of the band is roughly uniform because of the corresponding decrease in cortical magnification factor. In addition, for the wedges at different angular locations, the widths of the bands should be similar because the cortical magnification factor at a particular eccentricity is approximately constant across different angles. As will be shown in Figure 7.7, these assumptions are valid. As a result, only the posterior-anterior direction needs to be considered

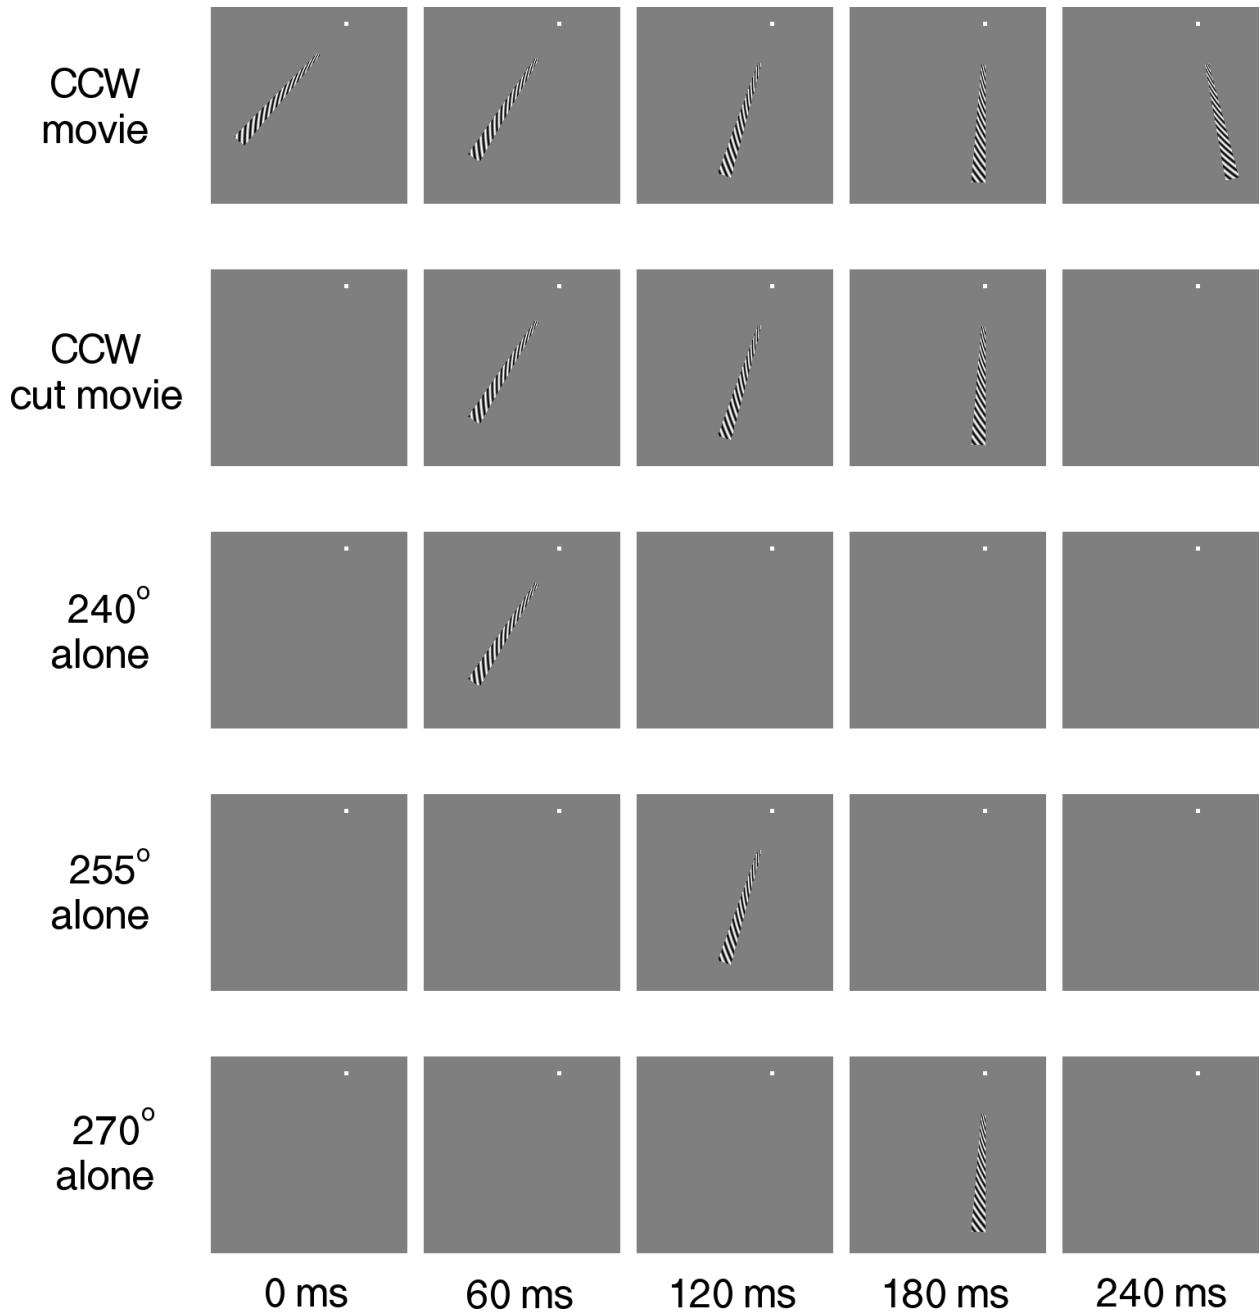

Figure 7.1: **Counterclockwise spatiotemporal stimuli in the VSDI experiment.** Each row in the figure shows snapshots of the stimulus at five example time points. The counterclockwise (CCW) movie always contained a wedge at some location. All the other stimuli were derived from the CCW movie by replacing some of the frames with a blank background. Each wedge was itself a stationary 100%-contrast grating, with decreasing spatial frequency toward the more peripheral location. The white dot in each snapshot is the fixation point.

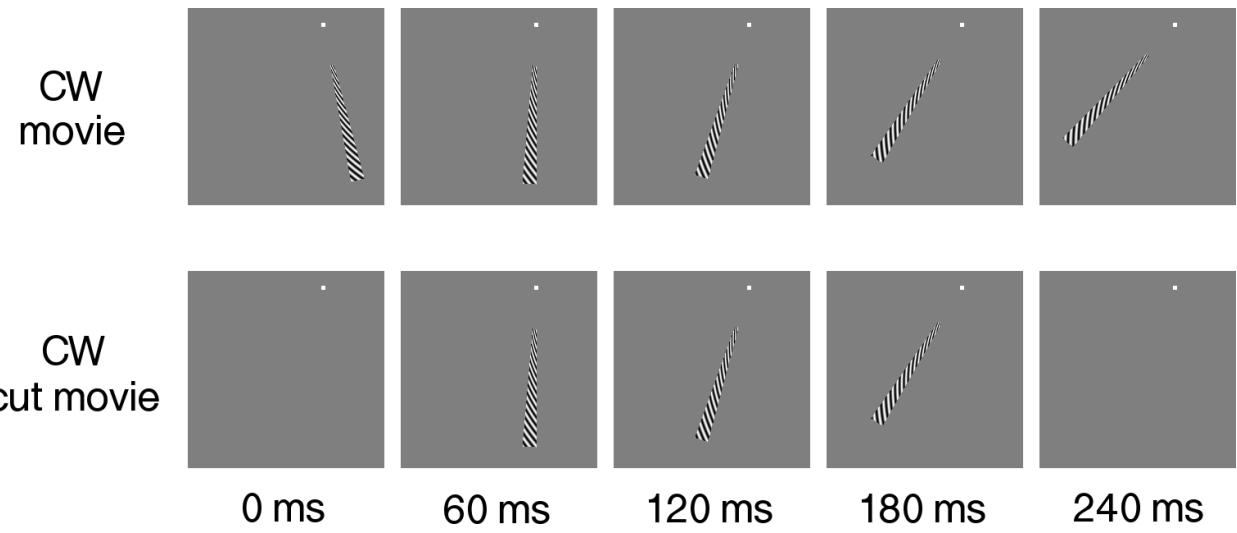

Figure 7.2: **Clockwise spatiotemporal stimuli in the VSDI experiment.** The clockwise stimuli are simply the counterclockwise stimuli in Figure 7.1 running backwards. For the full CW movie, the wedge started at  $285^\circ$  and rotated toward  $225^\circ$ . In the cut movie, the wedges outside  $240^\circ$  to  $270^\circ$  were replaced by uniform background, as in the corresponding counterclockwise stimuli.

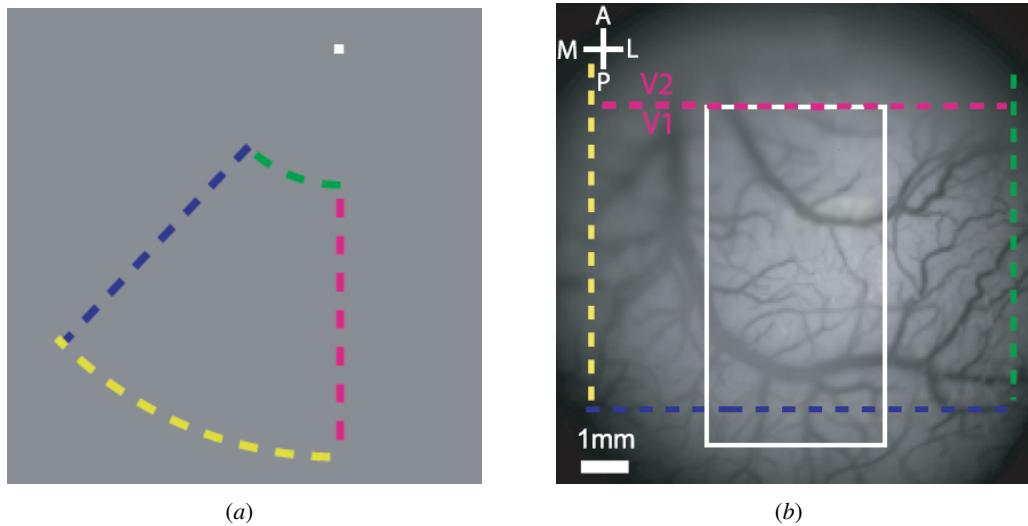

Figure 7.3: **Retinotopic mapping of the stimulus.** (a) A fan-shape outline that delineates the movie stimulus in the left visual field. (b) Image of the cortical vasculature taken through the imaging camera in a VSDI experiment. The four colored dashed lines show the approximate cortical representation of the corresponding lines in (a). Magenta line indicates the V1/V2 border. White rectangle is the  $4\text{ mm} \times 7.5\text{ mm}$  region plotted in Figure 7.7. Figures adapted from Yang et al. (2007).

and a wedge in the stimulus can be conveniently represented in the model as a pulse of appropriate width in the one-dimensional input layer, which represents the stimulus in cortical coordinates after retinotopic mapping (Section 5.1.1).

Based on the VSDI responses of such stimuli (which will be presented in Section 7.4.2), the width of the pulse is 0.7 mm in the input layer. As the wedge rotates counterclockwise, the pulse shifts in 0.7 mm steps toward location 0, which corresponds to the V1/V2 border. The clockwise stimuli will move in the opposite direction. Rotation of the wedge in the visual space is therefore mapped to translation in the input layer.

The second property of such stimuli is that after the wedge crosses the vertical meridian ( $270^\circ$ ), the neural response will “move over” to the other hemisphere. In other words, there is a boundary for the response at  $270^\circ$ . In the model, the vertical meridian therefore corresponds to one end of the modeled region and the wedges in the ipsilateral side are not represented.

### 7.3.2 Qualitative analysis

To understand the spatiotemporal dynamics of the responses in the model, first consider a fixed unit in the middle of the first stage. Suppose the pulse in the input layer starts at a certain distance from the unit and moves toward it. Before the pulse lands on the unit’s location, it will first fall partially in the unit’s receptive field. The response of this unit therefore starts to rise. Because the pulse may take several 20-ms steps to move from the periphery to the center of the receptive field, response can build up significantly before the pulse reaches the unit. On the other hand, responses for the single-pulse stimulus presented at the unit’s location can only start after the pulse appears. The response of the unit therefore rises earlier in the movie than in the single-pulse stimulus, resulting in a shorter response latency.

The distance between the location of the unit and the first pulse determines how much faster response will rise. If the pulse starts at the unit’s location, the response will not be faster than that when it is presented alone. On the other hand, if the unit is far from the pulse, the response can already be quite large by the time the pulse reaches the unit. The further the unit from the first pulse, the faster its response. As a result, from the position where the pulse starts moving, the relative latency decreases at the locations along the trajectory of the pulse.

The upper bound of the latency decrease is determined by the size of the receptive field. Since the pulse moves at a constant speed, the receptive field size limits the time for the pulse to travel from the periphery to its center. Hence, after a certain time into the movie, the relative latency will be constant for the rest of the locations through which the pulse passes.

After the pulse reaches the center of a unit, it continues its motion and moves away. The receptive field summation at the unit therefore decreases gradually, which prolongs the response.

The above analysis applies similarly to the second stage of the model. In summary, the model predicts that the response for a movie at a particular location will have a shorter latency than that for the stationary wedge. The relative latency between these two conditions is predicted to increase at the locations along the wedge’s motion and is limited by the receptive field sizes.

### 7.3.3 Simulation results

The above analysis was verified with simulation; the results will be described in this section. To characterize the spatiotemporal responses, the latency difference between the response for the moving wedge and the

single-wedge stimuli will be determined for different locations, allowing quantitative comparison with the VSDI responses.

## Model simulation

A 7.5 mm long strip of V1 that corresponds to the collapsed white rectangle in Figure 7.3b was simulated. The strip started at the V1/V2 border at location 0 and ran perpendicular to the border in the posterior direction. The stimulus duration was 960 ms (four cycles). The parameters of the simulation were:  $\sigma_{R,1} = 0.63$  mm,  $\sigma_{N,1} = 0.9$  mm,  $C_1 = 3.19$ ,  $C_2 = 2.3$ ,  $k_1 = 1089$ , and  $k_2 = 2$ . The widths of the receptive field and normalization pool were smaller than those in the simulation of spatial interaction described in Section 6.2.3 while the rest of the parameters were the same. The smaller widths were due to the narrower spatial spread of the VSDI responses for this stimulus, which will be discussed in Section 7.4.2.

## Spatiotemporal responses

Figure 7.4 shows the first 800 ms of the model's spatiotemporal responses for the counterclockwise stimuli shown in Figure 7.1. The format of the plots is the same as Figure 4.4. Only the top 4.5 mm of the modeled region is shown in the figure to compare with the VSDI responses shown later in Figures 7.8 and 7.9. As the pulse in the CCW movie moves from 225° toward 285°, it elicits responses that shift up with it. After it passes through 270° (0 mm), the pulse is in the other side of the visual field. The resulting responses will be in the other hemisphere of V1, which is not included in the model.

For the CCW cut movie, in each cycle, the first pulse appears at 3.5 to 4.2 mm and there is no response at these locations before that time. On the other hand, the responses at these locations for the full stimulus have already started to rise because of the previous pulses that appear in earlier locations, as analyzed in Section 7.3.2. This difference can be easily seen from the responses for these two stimuli at 800 ms. The responses for both stimuli at locations around 0 are roughly similar because of the limited receptive field size. Pulses that appear outside of the receptive field do not contribute to the response, therefore to the units near location 0, the two movies and hence their responses are the same. In addition, note that for these units, the normalization pools are truncated beyond location 0, the boundary of the model region. The lower normalization activity at these locations results in larger peak responses than the other locations.

Each of the bottom three panels in Figure 7.4 shows the spatiotemporal responses to a different single-pulse stimulus. The responses at around 4.2 mm for the stimulus containing a wedge at 240° alone begin to rise at the same time as with the cut movie, and later with the full movie. For the 255° and 270° stimuli, the the responses at their peak locations are delayed compared to those for the movie stimuli. The relative latency of the responses therefore decreases more as the pulse travels, as discussed in the previous section. Note also that the amplitude of the response at the peak location is only about 20% smaller than the peak amplitude in the movie.

Figure 7.5 shows the spatiotemporal responses for the two clockwise movies. The stimuli and hence the responses are the same during the initial part of the cycle. The wedge in the cut movie disappears after reaching 240° and the responses drop together at all locations, as in the case for a briefly presented stimulus discussed in Chapter 5. In the full movie, the pulse continues to move beyond 240°. Because of the spatial spread of the responses, the falling edges are prolonged, as in the previous locations. The model therefore predicts that the relative latencies of the two movies to be the same at most locations.

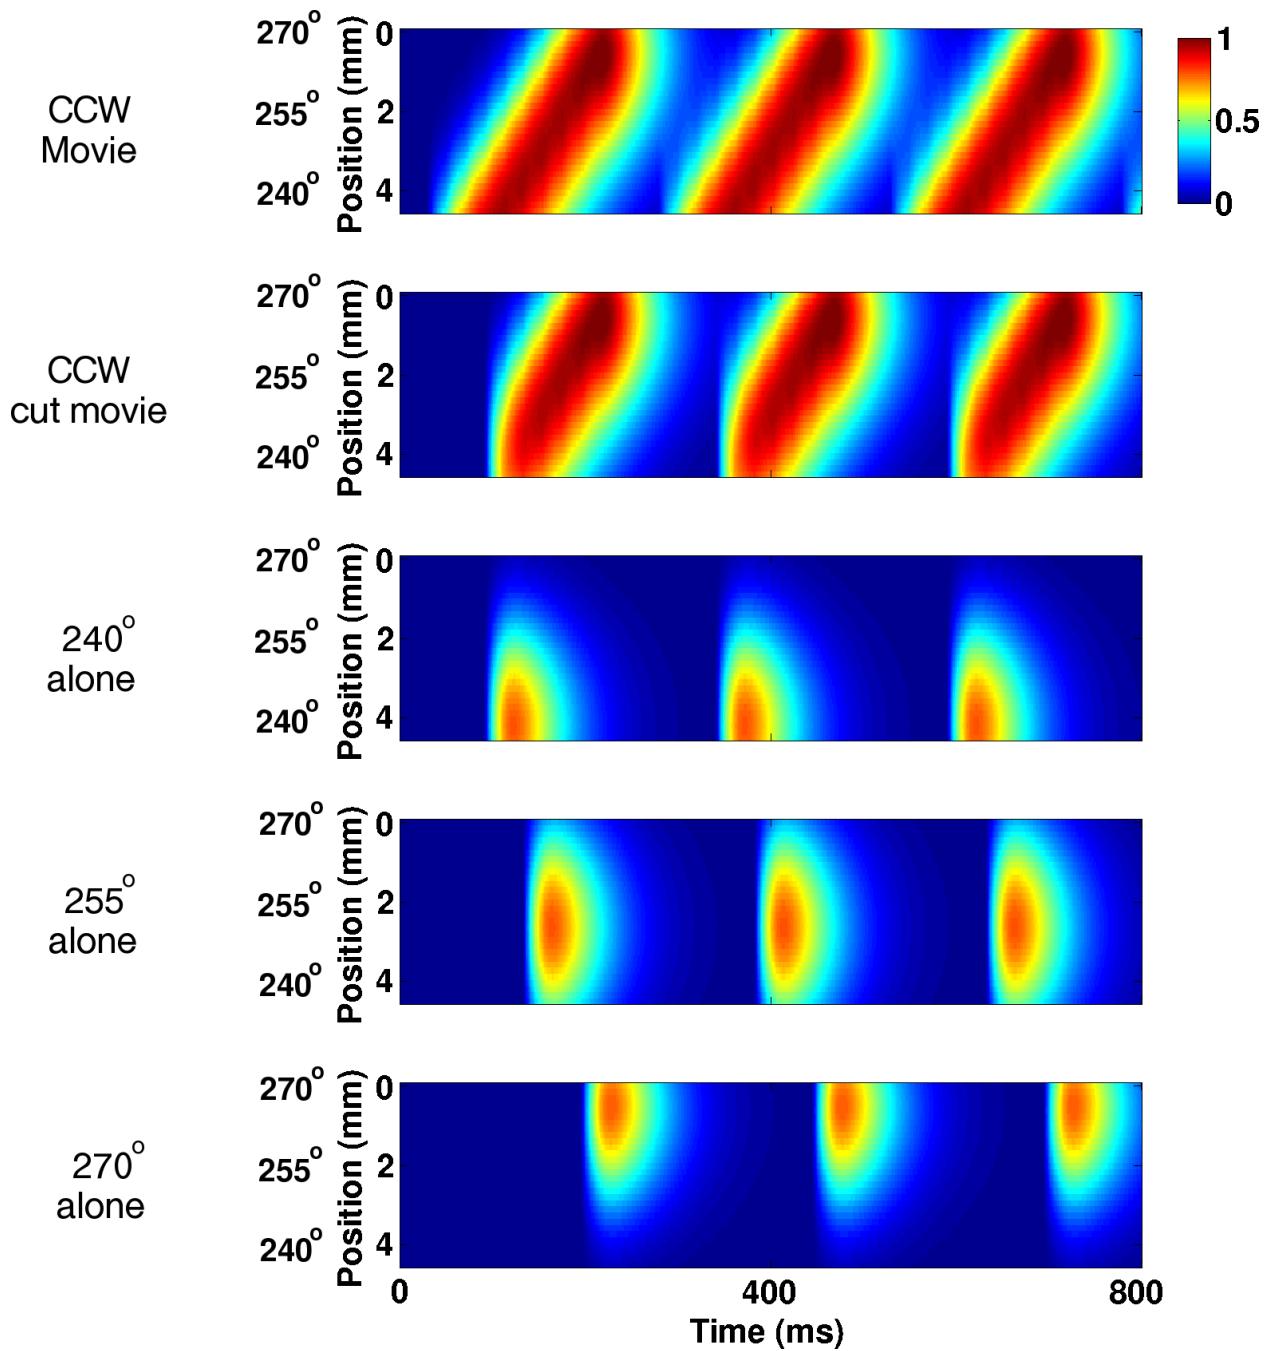

Figure 7.4: **Spatiotemporal responses of the model for the counterclockwise stimuli.** Each subfigure plots the responses for the first 4.5 mm of the modeled region. The corresponding visual angles of three key locations are shown to the left of the  $y$ -axis. The responses in all the plots are normalized by the same factor. The responses at around 4.2 mm ( $240^\circ$ ) start to rise earlier than those for the cut movie and the  $240^\circ$  pulse alone because the pulses presented earlier fall into the receptive fields at these locations. As time progresses, the responses for the two movies become more and more similar. Both of the responses begin to rise earlier than the single pulses presented at  $255^\circ$  and  $270^\circ$ . The latencies of the responses for the movies and the single pulse at the same location are therefore different.

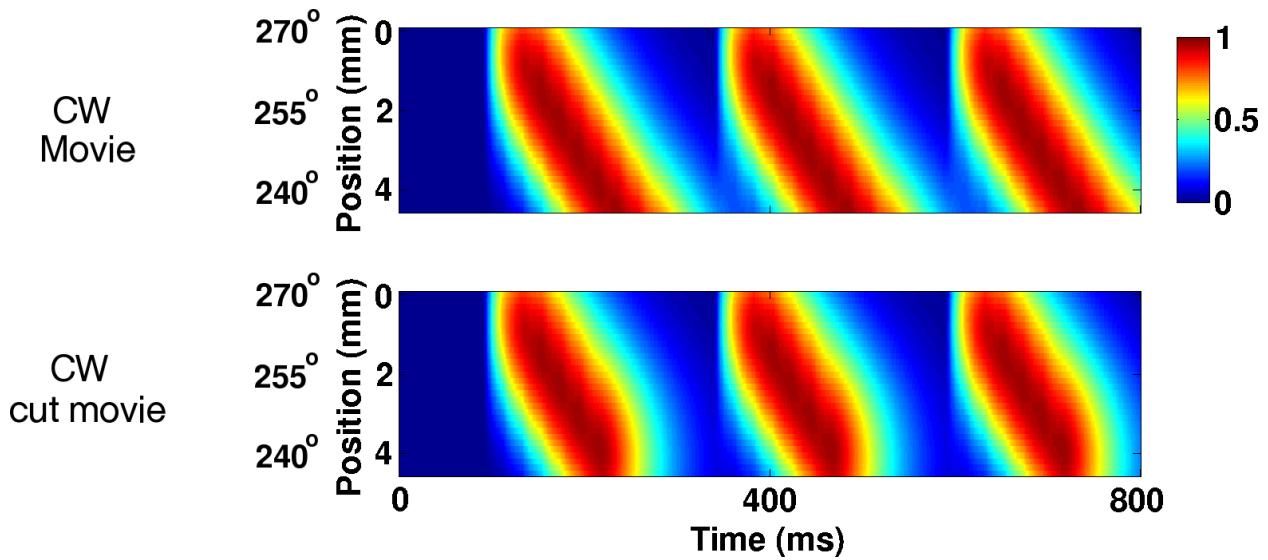

Figure 7.5: **Spatiotemporal responses of the model for the clockwise stimuli.** The responses for the two movies are initially the same because the stimuli are the same. The cut movie stops at  $240^\circ$  and the responses drop together at all locations. In the full movie, the pulse continues to move beyond  $240^\circ$ , thus extending the falling edges at those locations. The responses are therefore different at these locations.

### Relative latencies

To compare the time courses of the responses for the movies quantitatively to those for the single-pulse stimuli, the fast Fourier transform was applied to the response at each location for each stimulus to obtain the phase of the response at the stimulus frequency (4.17 Hz). Then, for each location, the phase of the response for the single-pulse stimulus that appears at that location was subtracted from that of the movie stimuli. Finally, this difference in phase angles was converted into time from the length of the stimulus cycle to produce the relative latency. A relative latency of 0 ms at a particular location means that the responses for the movie and the corresponding single-pulse stimulus are in phase. A negative relative latency means that the response rises earlier for the movie than for the single pulse. The main reason of employing such a measure of response latency instead of the one used in Section 4.3.2 (i.e. time to rise above 10% of the peak response of the sigmoidal fit) is to compare the model’s predictions with the VSDI responses. Unlike the experiment in Chapter 4, the number of trials for these stimuli was small ( $\sim 10$ ) and the Fourier components of the VSDI responses provided a much larger signal-to-noise ratio than the raw time courses.

Figure 7.6a shows the relative latencies at different locations for the counterclockwise movies. At 4.2 mm ( $240^\circ$ ), the latency is already decreased by about 12 ms for the full movie because of the earlier pulses. The relative latency is about 0 ms for the cut movie because this is the location where the first wedge appears in the stimulus. As the pulse moves closer to location 0 ( $270^\circ$ ), the relative latencies of both stimuli decrease because there are more pulses in earlier locations to increase the response sooner. Finally, the relative latencies for the two stimuli converge because receptive fields have limited size as discussed in Section 7.3.2.

Figure 7.6b shows the relative latencies for the clockwise movies. At the beginning ( $270^\circ$ ), the relative latencies for both stimuli are 0 ms because no pulse has yet been presented in the cycle. As in the counterclockwise stimuli, the relative latency decreases at locations along the motion of the pulse. The two relative latencies are the same up to about 2 mm ( $255^\circ$ ) because the first parts of the movies are the same

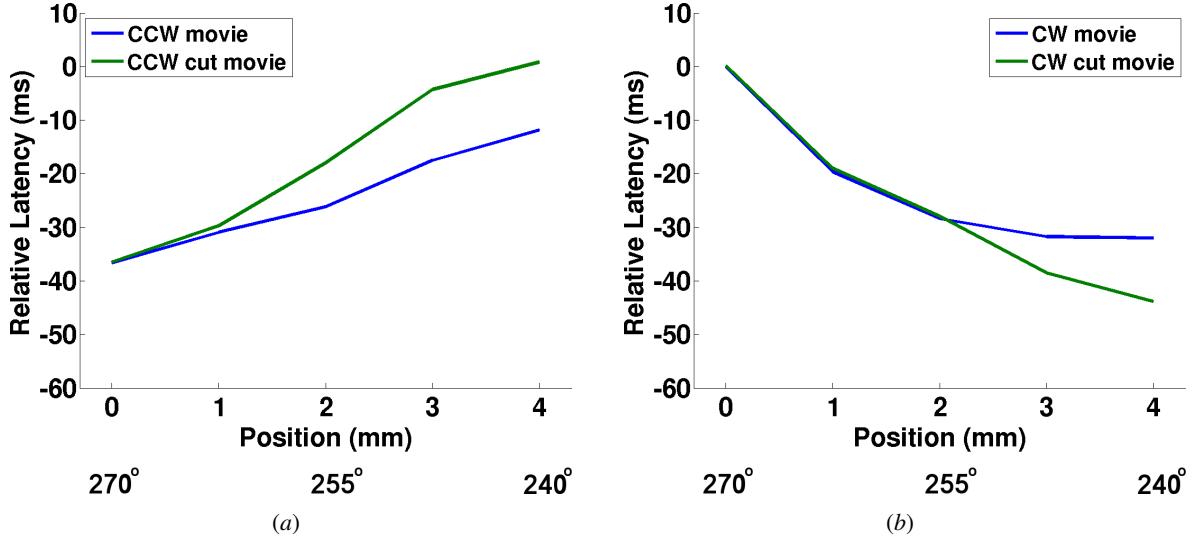

Figure 7.6: **Relative latencies of the responses.** (a) Relative latencies for the counterclockwise stimuli. As shown in Figure 7.4, the latencies for the full movie and the cut movie are different initially at around 4.2 mm. For the cut movie, the relative latency is zero because it is the first location that the pulse appears. The relative latencies for both stimuli fall as the pulse moves toward 0 mm and they finally converge as the corresponding responses become the same. (b) Relative latencies for the clockwise stimuli. Initially, the relative latencies for the full movie and the cut movie are the same. They start to diverge as the relative latency for the full movie stabilizes, whereas for the cut movie, it decreases as there are fewer pulses moving away to delay the relative latency.

in the modeled hemisphere (Figure 7.2). The relative latency for the full stimulus stabilizes during the later part of the movie because of the limited receptive field size; a steady relationship between the responses to the full movie and the single pulse stimuli has been reached. For the cut movie, there is a further drop in relative latency at locations near the end because the responses at these locations are shorter than those for the full movie (Figure 7.5). The peaks of the response hence occur earlier, resulting in larger decrease in latency because the phase of the Fourier component is closely related to the time-to-peak of the response.

In summary, the model predicts that after the movie has started, the latency of the response is decreased relative to that for a single wedge presented at the same location. Such decrease is due to the previous wedges in the movie because the responses to the first wedge are not accelerated (Figure 7.6a). On the other hand, the wedges that appear later in the movie counteract with such decrease. When the movie stops, such counteraction disappears, resulting in a larger latency decrease (Figure 7.6b). These predictions will be compared with the VSDI responses next.

## 7.4 VSDI experiment

In this section, the details of the VSDI experiment will be described, followed by the same analyses of the population responses that were applied to the model's responses.

### 7.4.1 Experimental procedures and data analysis

The stimuli shown in Figures 7.1 and 7.2 were presented to a fixating monkey as a part of an experiment to obtain a precise retinotopic map of V1 with VSDI (Yang et al., 2007). This animal is different from those

in the experiments described in the previous chapters. In each trial, seven cycles of the same stimulus were presented, for a total of 1680 ms. The length of the wedge spanned from  $1.32^\circ$  to  $4.2^\circ$  visual angle, i.e.  $2.88^\circ$  long. In the experiment reported in this section, there were 11 trials for each condition.

The VSDI signals were processed by the procedures that were similar to those described in Section 4.2.2. The region of interest (ROI) where the VSDI signals were analyzed is shown in Figure 7.3b. As was discussed in Section 7.3.1, the response to a wedge in V1 is a band of roughly uniform width along the lateral-medial direction, which is horizontal in this region. The VSDI signals were subsequently averaged across the width of the region to obtain a one-dimensional response.

The top of the ROI was located roughly at the V1/V2 border (vertical meridian), which can be estimated from the VSDI responses of the movie stimulus. Due to the symmetric but opposite mappings of polar angles in V1 and V2, as the wedge rotates toward the vertical meridian, the responses in these two areas move toward each other. When the wedge is at  $270^\circ$ , i.e. vertical, these two responses converge. The line of convergence thus corresponds to the V1/V2 border.

To derive the relative latencies of different stimuli, for each location and for each trial, the Fourier phases of the time courses at the stimulus frequency (4.17 Hz) were extracted after removing the average signal of the blank condition.

## 7.4.2 Results

In this section, the peak spatial responses for stimuli consisting of a single wedge will be presented first to show the mapping of the wedges on V1. After that, the spatiotemporal responses and their relative latencies will be presented. The properties of the VSDI responses are consistent with the model's predictions, suggesting that population gain control is a general mechanism for visual processing.

### Peak spatial responses for single wedges

Figure 7.7 plots the normalized peak spatial responses in the region of interest (white rectangle in Figure 7.3) for the stimuli that contained only a single wedge at the labeled location. As can be seen in the plots, the responses form horizontal bands of roughly uniform width. The average width ( $\sigma$ ) of the Gaussian fits for the spatial responses for all vertical slices is 1.05 mm, which is narrower than those observed in the experiments discussed in previous chapters (2.1 mm). Such difference may be due to the variations in individual animals and is unlikely to be due to the widths of the stimuli because they are all very small.

Each time the wedge was rotated by  $30^\circ$ , the corresponding responses shifted by about 2.1 mm. The mapping of polar angle to the cortex is hence approximately linear. A distance of 5 angular degrees therefore maps to 0.7 mm, which was used as the width of the pulse in the input layer of the model.

Because the VSDI responses are similar in the horizontal direction, they were averaged and collapsed into one-dimension responses that ran vertically from the V1/V2 border in the posterior direction, which is the region that the input layer of the model represents.

### Spatiotemporal responses

The average spatiotemporal responses of the collapsed region for different counterclockwise stimuli are plotted in Figure 7.8. Only the responses in the top 4.2 mm of the ROI were plotted because the responses in the bottom part are noisy. The first 800 ms after stimulus onset are shown, and all the responses were normalized by the same scale. As predicted by the model, the responses at around 4.2 mm from the V1/V2

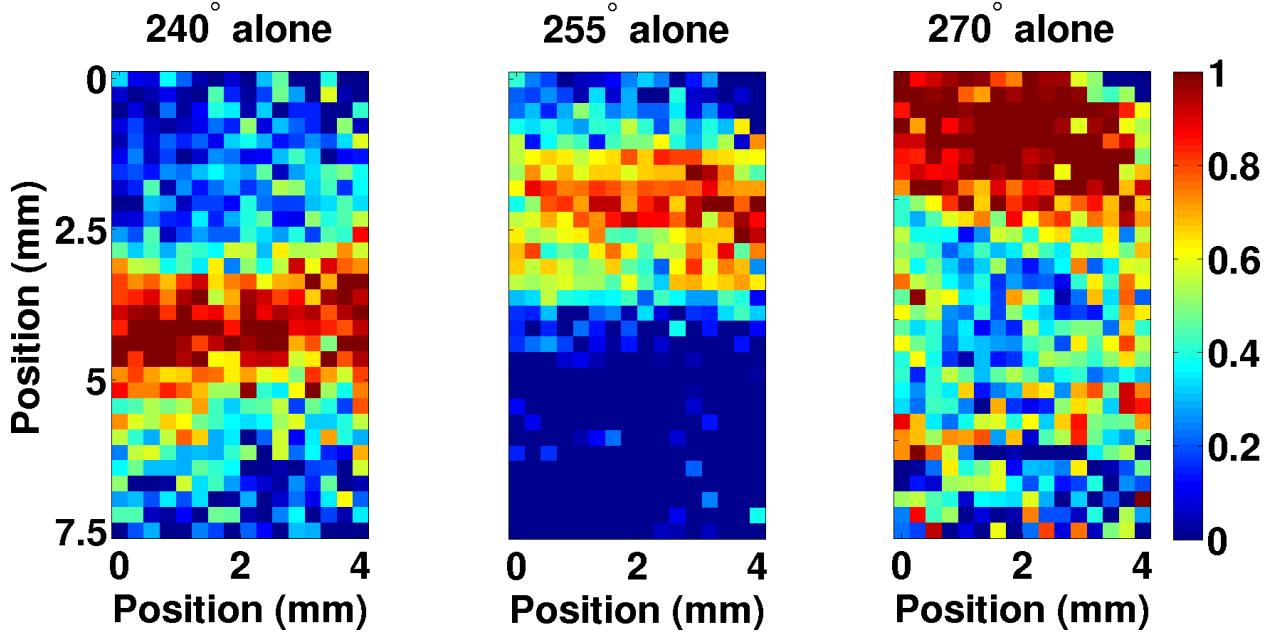

Figure 7.7: Normalized peak spatial responses for the three single-wedge stimuli. The region shown corresponds to the white rectangle in Figure 7.3b. The responses form approximately horizontal bands of similar widths, hence only the responses along the vertical direction need to be considered in the analysis. All the responses are normalized by the same factor.

border started to rise earlier in the full movie than in the cut version. In addition, the responses for the single wedge presented at  $240^\circ$  at these locations were similar to those for the cut movie, which is also consistent with the model.

The responses moved up as the wedge rotated. At locations around 0, the responses for both movies were similar; they rose, peaked, and fell at about the same time. On the other hand, the responses at these locations for the single wedge at  $270^\circ$  started to rise at a much later time, as predicted by the model. The amplitude of the peak response for the single wedge is about 15% smaller than that for the movie stimuli, which is also similar to the model's prediction.

Figure 7.9 shows the average spatiotemporal responses for the clockwise movies. In the cut movie, there was a large baseline component that increased the response at all locations substantially. The normalized responses did not fall back to zero between cycles and they were larger than one most of the time in many locations. Nevertheless, the rising edges of both responses appear to be similar in the first cycle, which is consistent with the model's prediction.

The spatiotemporal responses for these stimuli thus seem to agree with the model's predictions qualitatively.

### Relative latencies

The variations in the responses in different cycles and the large baseline activity in the responses for the clockwise cut movie are mainly due to noise at low frequencies, such as the artifact from heartbeat. The noise, as estimated from the power spectrum of the blank trials, has relatively low energy at the stimulus frequency. A higher signal-to-noise ratio can therefore be obtained from the Fourier component at the stimulus frequency than from the raw time course of the response. The latencies of the responses were

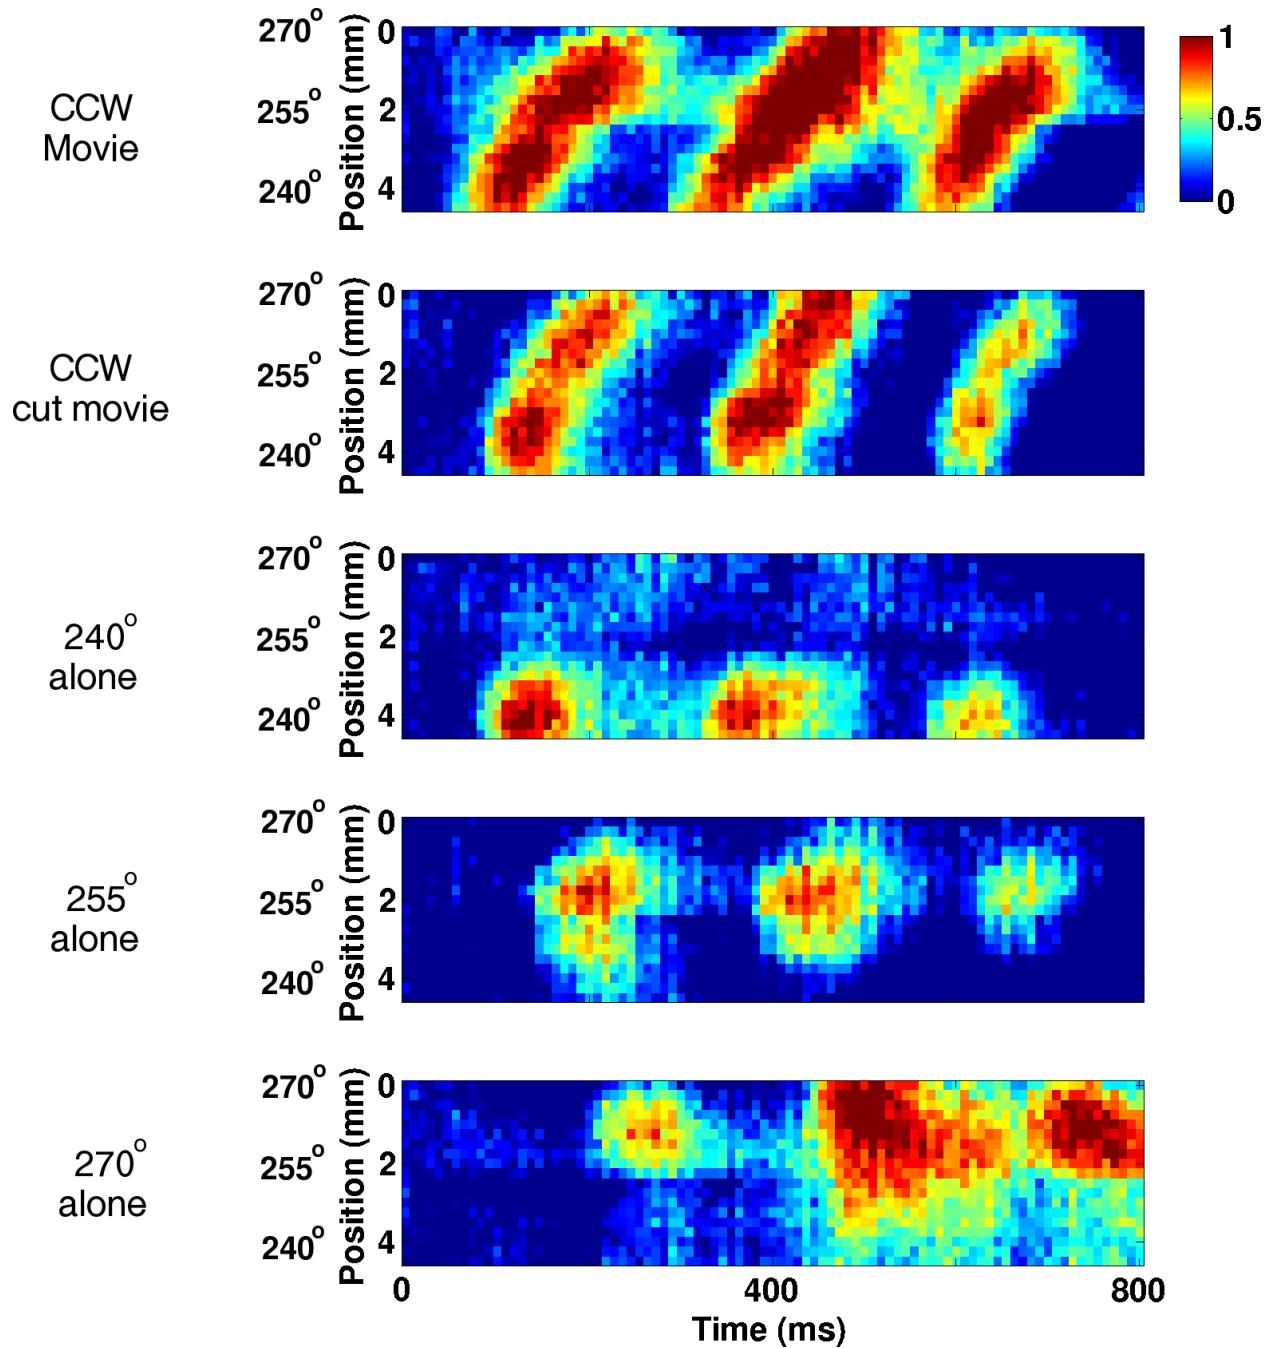

Figure 7.8: **Spatiotemporal VSDI responses for the counterclockwise stimuli.** The responses are normalized by the same scale as in Figure 7.7. The responses for the full movie start to rise earlier than those of the cut movie and the  $240^\circ$  wedge at around 4.2 mm. At around 0 mm, the responses for the two movies are similar and rise earlier than the  $270^\circ$  wedge. The model's predictions (Figure 7.4) are therefore consistent with the VSDI responses.

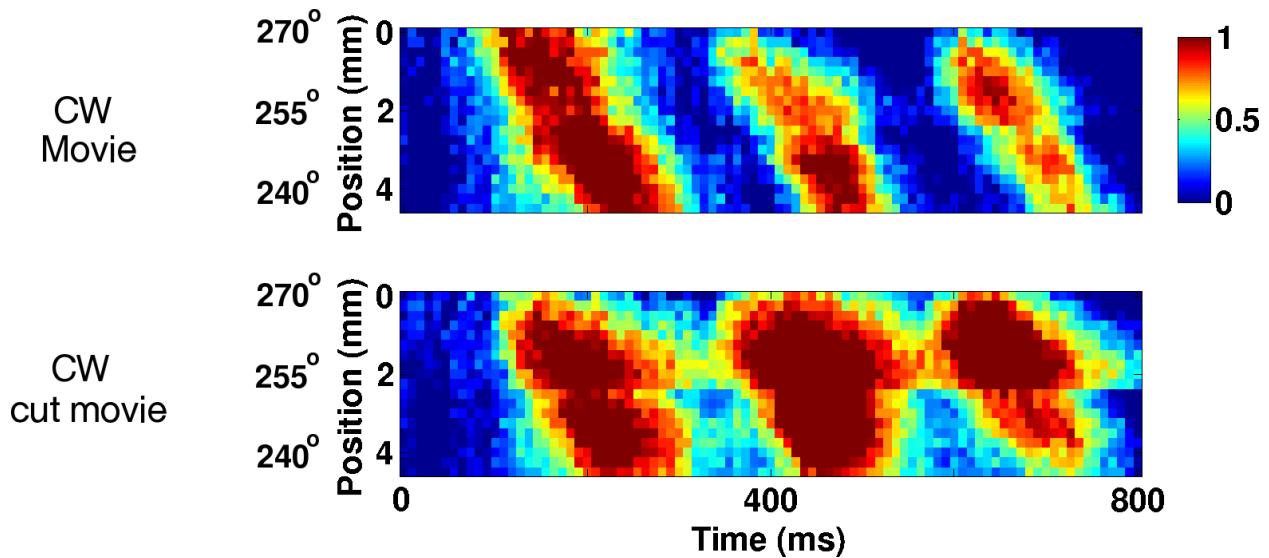

Figure 7.9: **Spatiotemporal VSDI responses for the clockwise stimuli.** There is a large baseline noise for the cut movie between 200 to 700 ms, saturating the color scale. The noise has mostly low frequency, and a higher signal-to-noise ratio can be obtained by considering the Fourier amplitude at the stimulus frequency to compute the relative latencies as in Figure 7.10.

hence estimated using the phase of that Fourier component.

The relative latencies for different movie stimuli of the VSDI responses were computed using the same method used for the model’s responses. There were only three single-wedge locations tested in the experiments. The latencies of these responses were interpolated to estimate the latencies at the locations in between them. In addition, since the timing for the single-wedge stimuli matched only the counterclockwise movies, the latencies of these stimuli for the clockwise timing were estimated from those at the mirror locations of their counterclockwise counterparts.

Figures 7.10a and b plot the relative latencies at different locations for the counterclockwise and clockwise movies, respectively. The error bars are the 95% bootstrap confidence intervals and the solid lines are the predictions of the model in Figure 7.6. These lines lie within the confidence intervals for all stimuli at all locations, suggesting that the model provides an accurate description of the spatiotemporal dynamics of VSDI responses for the movie stimuli.

To investigate whether the decrease in latency can be explained solely by linear receptive fields, a model that uses the average VSDI responses to a single  $255^\circ$  wedge as the “spatiotemporal impulse response” to a single wedge was simulated. For each wedge in the movie, the impulse response was added to the model at the corresponding time and space to produce the response. The relative latencies of this model are plotted in dashed lines in Figure 7.10, which have a similar behavior to the data, suggesting that the decrease in response latency in the movies could be accounted for to a large extent by linear receptive fields. However, the responses in the linear model for a movie can be three times larger than that for a single wedge because of the spatial spread of the responses. The difference observed between the amplitudes of these two responses is only 15%, which is inconsistent with the linear model. On the other hand, because of gain control, the responses for the movies in the PGC model are only 20% larger than those for a single wedge. This result demonstrates the important role of normalization: It keeps the response within the dynamic range.

Normalization also contributes to the decrease in latency in the second stage of the model. Because

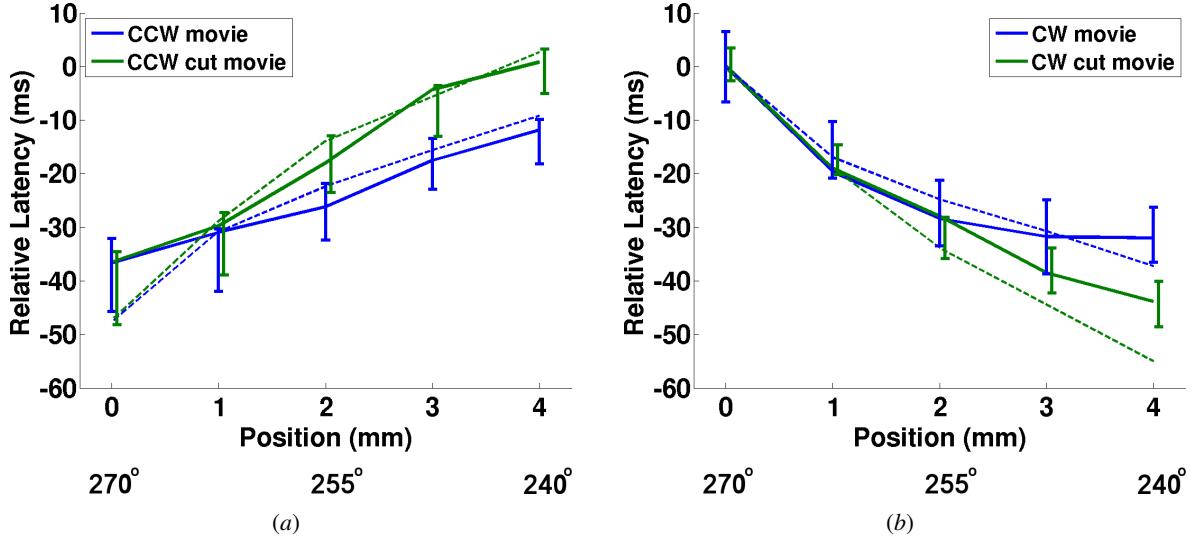

Figure 7.10: **Relative latencies of the VSDI responses and the model’s predictions.** Error bars are 95% bootstrap confidence interval. The solid lines are the predictions of the model from Figure 7.6. The dashed lines are linear predictions based on the VSDI responses to a single wedge. The model’s predictions are consistent with the data, suggesting it is a general model of visual processing.

the response time courses are continuous in the first stage, the spatial normalization pool of the second stage will include the first-stage responses elicited by previous pulses. At a particular location, the normalization activity will build up over time as the pulse moves toward it. As a result, the time constant of the rising edge of the response will be smaller than that for the single pulse, leading to a shorter latency. In the first stage, the normalization pool does not include activity from previous pulses because the input activity simply turns on and off instantly as the pulse moves along the input layer.

## 7.5 Discussion

The PGC model can account for the spatiotemporal dynamics of V1 population responses simultaneously for different stimuli

### 7.5.1 Model parameters

The shorter response latency in moving stimuli reported in this chapter has also been observed in the retinal ganglion cells of the salamander and rabbit using similar stimuli (Berry, Brivanlou, Jordan, & Meister, 1999). This result suggests that some of the latency decrease observed in V1 may come from subcortical areas. Coincidentally, a single-site contrast gain control model similar to PGC was used to account for such latency decrease in the retina (Berry et al., 1999), echoing the idea that gain control occurs in multiple stages in the visual pathway, as discussed in Chapter 5. To model the responses in V1, it is therefore inaccurate to assume that subcortical areas are linear, as they are in many models.

Interestingly, the decrease in response latency for a moving stimulus is consistent with a visual illusion called the flash-lag effect in which a flash and a moving object that appear in the same location are perceived to be displaced from one another (Mackay, 1958; Nijhawan, 1994; Whitney & Murakami, 1998;

Eagleman & Sejnowski, 2000). If response latency alone is used to determine the timing and position of the stimulus, the flash-lag effect will be smaller if the moving object travels for a shorter distance before the flash object is presented because the relative latency is smaller. On the other hand, the same argument implies that the initial motion of the moving wedge will be perceived as slower because the limit of decrease in latency has not yet been reached. This implication seems unlikely and more experimental and computational studies are required to understand how motion and position are perceived.

## 7.6 Conclusion

In this chapter, the PGC model was applied to moving stimuli. Such stimuli constitute a challenging test for the generality of the model, which was based on the observations in the responses of small stationary stimuli.

The model predicted that the responses in a movie would have a shorter latency than a stationary wedge at the same location. The relative latency between these two conditions was predicted to increase in locations along the wedge's motion and was limited by the receptive field sizes. These predictions were found to be consistent with the VSDI responses of such stimuli. Specifically, the values of the relative latencies at different locations for the full movies and their cut versions agreed with the model's predictions. The relative latencies for different parts of the movie can therefore be explained by the PGC model.

The PGC model is the first model that can account for the spatiotemporal dynamics of V1 population responses simultaneously for different stimuli containing (1) a single Gabor element, (2) two Gabor elements, and (3) a wedge that rotates at constant speed, suggesting that it is a general, accurate, yet simple model for visual processing.

# Chapter 8

## Discussion and Future Research

The results in the previous chapters show that the PGC model in which a unit represents a local population of neurons with different stimulus preferences can account for the spatiotemporal responses in V1 for different types of stimuli. For each of the stimuli, different receptive field and normalization pool sizes were used in the model simulation. Moreover, the current model does not take into account fine-scale cortical structure, such as orientation columns. This chapter discusses the issue of using different model parameters for different stimuli first, and then outlines how fine-scale structures can be modeled in future work and proposes further research directions with such an extension. More specifically, the extended model can be used to (1) (1) analyze the network's stability, (2) study the neural code for orientation, (3) investigate how the model can be extended to development, and (4) how it can be used to simulate high-level areas.

### 8.1 Model parameters

In the simulations of the model, the receptive field and normalization pool sizes were different for the three classes of stimuli used in Chapters 5, 6, and 7, due to the different spatial spreads observed in the VSDI responses. It is possible that such difference in sizes is mainly due to individual variations between the animals, as a different animal was used in each experiment. Another possibility is that for different stimuli, slower processes such as adaptation and homeostasis may take place and change the operating point of the neural population. However, given the relatively short stimulus presentation ( $\sim 1$  s) and long intertrial interval (6-8 s) for all the stimuli, these processes should result in similar operating points. In addition, the monkeys were only required to maintain fixation in all the experiments, hence any high level task-related modulations in V1 should be similar and should not affect the sizes of the receptive fields and normalization pools.

A straightforward way to test these arguments is to use a single animal with the three classes of stimuli. If the spatial spreads of the VSDI responses are the same and a single set of model parameters can be used to account for the responses, it will support the argument that the difference reported in this dissertation is due to individual variations. Otherwise, more investigations will be required to study how the operating points of the neural population change with stimuli and how the model can be extended to account for it.

Finally, the change in parameters may be due to other mechanisms that the model omits, which cause relatively small errors for the specific experimental data shown in this dissertation. As in any model, these omitted mechanisms may turn out to be important and prevent the model from being valid in general over

a wide range of conditions. Further experiments using different types of stimuli are required to address this important question.

## 8.2 Extension to fine spatial scales

A unit in the PGC model represents a local population of neurons that spans several orientation columns. Extending the PGC model to the orientation-column level is therefore a logical and important next step. Such an extension will require that the connectivity in V1 is represented in detail: There are extensive lateral and feedback connections in V1 that link neurons with similar orientation preference and presumably play a role in information processing (Fisken et al., 1975; Gilbert & Wiesel, 1979, 1983; Hirsch & Gilbert, 1991; Bosking et al., 1997; Angelucci, Levitt, Walton, et al., 2002). However, little is known about how exactly they do it. Extending the PGC model to include such connections should provide insight into this open question.

In the experiments in this dissertation, orientation-related signals are weak in the VSDI response because a relatively low spatial resolution was used to image the active region of V1. At a higher resolution (which is possible with current technology) the responses from individual columns will be stronger and the predictions of the extended model can be tested experimentally.

In this section, a possible representation of orientation-specific signals will be discussed, followed by an outline of different formulations that can incorporate such signals into the model. Extensions for other properties at fine spatial scales such as direction selectivity should follow similar formulations. The remaining sections of this chapter outline future research directions that the extended model makes possible.

### 8.2.1 Modeling orientation-specific signals in lateral and feedback connections

Orientation-specific signals occur only in the second stage of the model because the subcortical areas, which the first stage of the model represents, are not orientation-selective. All the variables in this chapter therefore refer to the second stage of the model and the first stage will remain the same.

In the extended model, a unit is labeled not only by its receptive field location  $x$ , as in the original PGC model, but also by its orientation preference  $\theta$ . In addition, the receptive field of a unit is a Gabor function with orientation  $\theta$ , instead of its Gaussian envelope. The receptive field can also be extended to model other response properties such as direction selectivity that the current PGC model does not take into account. The formulation of the model for these properties will be similar to the extensions discussed in this section.

Since the unit responses represent membrane potentials, they have to be transformed into spiking activity through a power function before sending them out to other units (Section 5.1.4). Connections between units are assumed to have the same pattern for all units represented by a spatiotemporal kernel  $G_o(x, \theta, t)$ . The spatial component of the kernel represents the connection weights from the units at different relative locations and orientation preferences, and the temporal component models the conduction speed of these connections. Thus, the orientation-specific signal  $R(x, \theta, t)$  received by the unit  $(x, \theta)$  at time  $t$  is

$$R(x, \theta, t) = V(x, \theta, t)^n \otimes G_o(x, \theta, t), \quad (8.1)$$

where  $\otimes$  denotes convolution.

### 8.2.2 Possible extensions of the PGC model for orientation-specific signals

One way to incorporate orientation-specific signals into the model is to treat them as external inputs, as in many previous models using LN units (Miikkulainen et al., 2005; Sirosh & Miikkulainen, 1994), and leaky integrators (Wilson & Cowan, 1973; Amari, 1977; Ben-Yishai et al., 1995; Somers et al., 1995; Hansel & Sompolinsky, 1998) that were reviewed in Chapter 3. More specifically, these signals are represented as an extra input current into the RC circuit of the model while the other variables remain the same. The extended model then becomes

$$C \frac{\partial V(x, \theta, t)}{\partial t} = R(x, \theta, t) + A(x, \theta, t) - g(x, t)V(x, \theta, t). \quad (8.2)$$

Note that the conductance  $g(x, t)$  does not depend on orientation because the normalization activity is assumed to be unselective for orientation in this extension, as in the original PGC model. Conductance that is a function of the orientation-specific signals will be discussed later in this section.

The dynamics of the responses impose constraints on the properties of the orientation-specific signals. For example, after the stimulus presentation, the driving current  $A(x, \theta, t)$  will be zero everywhere and equation 8.2 becomes

$$C \frac{\partial V(x, \theta, t)}{\partial t} = R(x, \theta, t) - g_0 V(x, \theta, t). \quad (8.3)$$

For the response to decay, the following inequality has to be satisfied:

$$R(x, \theta, t) < g_0 V(x, \theta, t) \quad (8.4)$$

$$V(x, \theta, t)^n \otimes G_o(x, \theta, t) < g_0 V(x, \theta, t). \quad (8.5)$$

One way to satisfy this inequality is to make all the components in  $G_o(x, \theta, t)$  negative, assuming the condition  $V(x, \theta, t) \geq 0$  is maintained in the model e.g. by rectification. In other words, the interaction is inhibitory.

Instead of changing the inputs directly, another possible role of the orientation-specific interactions is to adjust the conductance and hence the gain of the neurons. Such interactions can be additive, i.e.

$$g(x, \theta, t) = g_0(1 + B(x, t) + R(x, \theta, t)), \quad (8.6)$$

or multiplicative, i.e.

$$g(x, \theta, t) = g_0(1 + B(x, t))(1 + R(x, \theta, t)). \quad (8.7)$$

In the formulation 8.6 and 8.7, the orientation-specific signals increase conductance, which leads to faster temporal dynamics and a suppressed response.

It is also possible for these signals to affect both the input and the gain of the units. However, as a next step, it is useful to study them individually so that the resulting response properties can be characterized separately.

These extensions can be approximated by the original PGC model in certain cases where the orientation-specific signal is small. Anatomically, the lateral connections to nearby neurons are relatively unspecific, but at longer distances they tend to connect neurons with similar orientation preferences (Amir, Harel, & Malach, 1993; Malach, Amir, Harel, & Grinvald, 1993; Bosking et al., 1997; Sincich & Blasdel, 2001). For stimuli that consist of single small elements (such as those used in Chapter 4), these signals are similar around the center of the stimulus and are thus not orientation-specific. As a result, the conductance depends

only on  $x$  and  $t$  at these locations and can be written as  $g'_0(1 + B'(x, t))$ , which is of the same form as in the PGC model.

For stimuli consisting of two elements (such as those used in Chapter 6), the orientation-specific signals from one element will suppress the responses for the other element. Because of the conduction speed of the lateral and feedback connections, such an effect will have a delay that depends on distance. As a result, if the stimulus is presented periodically, for a certain range of separation, the suppression from one element can coincide with the falling edge of the responses to the other element, thus resulting in stronger modulation. The extended model could therefore explain the larger modulation observed in the VSDI responses at some separations (Section 6.2.4).

### 8.3 Analysis of the extended model

The delayed suppression in the extended model can cause oscillations in the responses when the kernel  $G_o(x, \theta, t)$  satisfies certain conditions, e.g. the suppression is too strong. While coherent oscillations have been observed in the spiking activity of a small group of neurons (see e.g. Jefferys, Traub, and Whittington (1996) and Buzsáki and Draguhn (2004) for review), VSDI responses do not seem to oscillate. One fundamental question for the extended model is therefore under what conditions the fixed points of the network are stable?

In fact, equation 8.2 is a generalization of the Hopfield network (Hopfield, 1982), whose stability has been analyzed thoroughly (Marcus & Westervelt, 1989; Belair, Campbell, & van den Driessche, 1996; Wang, Liu, & Liu, 2005; Liao, Liu, & Zhang, 2006; B. Chen & Wang, 2007; Shao, 2008). However, the conductance in a Hopfield network is constant, whereas in the extended model it depends on the pooled activity. It is therefore an open question how the stability analyses of Hopfield networks apply to a model described by equation 8.2. The conditions for stable fixed points will provide new insight on the general patterns of orientation-specific connections.

In addition, based on the stability conditions derived from the different formulations of interactions, new experiments can be designed to differentiate them, which should lead to a better understanding of the role of lateral connections in visual processing.

### 8.4 Decoding orientation-specific neural response

Chapter 6 demonstrated how the PGC model can be used to gain insight on how high-level areas may use the information available in the V1 responses to detect stimuli. A similar approach can be used with the extended model for orientation-related tasks.

The orientation tuning of most V1 neurons in the monkey is quite wide ( $\sim 25^\circ$  half-bandwidth; Schiller et al., 1976; De Valois et al., 1982; Ringach et al., 2002), however, a monkey can discriminate two gratings that differ by only  $2^\circ$  in orientation after training (Vogels & Orban, 1990). How can such a low threshold be achieved with responses that are so broadly tuned? Is there a best time window to integrate the response? These questions can be addressed by analyzing the responses of the extended model.

Another related future direction is to use the model's responses to design better decoders. The temporal integration method used in Chapter 6 is very simple. For a specific task, decoders that have a higher accuracy can be constructed by taking the spatiotemporal properties of the population responses and noise into account (Y. Chen et al., 2006, 2008). It is likely that the responses in V1 are used in different ways

for different tasks. Using a model that can represent the response dynamics accurately, efficient decoders can be built for a new task or stimulus without acquiring the actual neural responses for all possible conditions. One interesting potential application of such decoders is neural prosthetics, where the responses from the model can be used to train the controllers to read out the neural signals.

## 8.5 Network implementation of the model

Two-dimensional self-organizing networks have been successful in explaining how the orderly structure of the feature maps in V1 can develop in a network that is initially unorganized (von der Malsburg, 1973; Kohonen, 1982, 2001; Sirosh & Miikkulainen, 1994; Bednar, 2002; Miikkulainen et al., 2005). However, the units in these models do not take into account the temporal properties of the responses. By replacing these units with an implementation of the extended model, a self-organizing network with accurate response dynamics and lateral interaction can be built.

Such an extension is important because visual stimuli entering the eyes are constantly changing due to the motion in the environment and the observer's own movement. A model that can represent the spatiotemporal dynamics of the response accurately is therefore needed to study how selectivity and organization can develop in such conditions. In particular, many V1 neurons are selective to the direction of movement of the stimulus and an accurate description of response dynamics will be important to account for how such a selectivity arises.

## 8.6 Modeling higher level areas

Given the limited dynamic range of spiking activity, population gain control is a simple and effective mechanism that can maintain the sensitivity and tuning of neurons over a large range of sensory stimuli. It is therefore possible that population gain control operates in most, if not all, sensory cortical areas. Interestingly, a normalization model that is similar to the PGC model was used recently to reconcile alternative theories of attention (Reynolds & Heeger, 2009), suggesting that normalization occurs in high-level areas as well.

The visual pathway could therefore be simulated by a cascade of PGC models, each representing a functional area. Such a computational model would be important to understand the processing that takes place in each visual area after V1. In fact, little is known even for the immediate downstream area of V1, the secondary visual cortex (V2; Boynton & Hegde, 2004). Realistic computational models can be used to provide verifiable predictions on the receptive field properties and the computation that is carried out in these areas, and eventually allow us to understand the role of these areas in visual processing.

## 8.7 Conclusion

This chapter outlined future extensions based on the work in this dissertation, focusing on providing insight into visual processing at a more fine-grained level than in the current PGC model. In particular, theoretical constraints on the orientation-specific connections and their effects on the response dynamics can be derived from the extension. Such an extension can also provide insight into how high-level areas may use orientation-specific information in V1. In addition, detailed network models that have realistic response dynamics and interaction can be built to study how the orderly organization in V1 can develop through

input-driven self-organization. Such models can also provide verifiable predictions on the processing in higher-level areas, thus advancing our understanding of the visual system more broadly.

# Chapter 9

## Conclusion

The results in this dissertation show that even a simple stimulus can elicit a response that exhibits systematic and unexpected nonlinear properties. Most existing models are inconsistent with these properties. This dissertation proposes the population gain control (PGC) model, which is a generalization of normalization models. The PGC model can account for the spatiotemporal dynamics of the responses for a variety of stimuli, suggesting that population gain control is a general mechanism of cortical processing. It is therefore possible that population gain control operates in most, if not all, sensory cortical areas. If so, then the population dynamics reported in V1 may be observed in many other cortical areas as well, and the corresponding pathways may be understood computationally as a cascade of PGC models.

### 9.1 Contributions

In Chapter 4, the first quantitative description of the spatiotemporal dynamics of V1 population responses to a briefly presented localized visual stimulus was provided. The population responses exhibited systematic and unexpected nonlinear properties that are not obvious from single-unit recordings. These results demonstrate that unexpected properties can emerge at the level of neural populations, and that it is important to characterize population responses quantitatively in both space and time. More importantly, these properties are not consistent with most existing models of neural computation, suggesting a new model is required to account for them.

Chapter 5 showed that a simple canonical PGC model can account for the spatiotemporal dynamics of the response to a small stimulus. The PGC model was also used to address the outstanding question regarding the degree to which nonlinearities in V1 responses are inherited from its inputs. The PGC model predicts how the responses to a large stimulus depend on the nonlinearity in V1 and its input. Results from an additional VSDI experiment that varied stimulus size were consistent with the hypothesis that most of the response nonlinearity observed in V1 is inherited from its input. This result suggests that most of the gain control for a small localized stimulus may be implemented before the superficial layers of V1. It also illustrates how a computational model can be used not only to replicate the behavior of the responses, but to gain new insight about visual processing as well.

Chapter 6 discussed the predictions of the PGC model for V1 population responses to more complicated spatial stimuli that contain two elements. The model was used to pinpoint a small set of stimuli that was expected to be most informative for characterizing the interactions between the two elements. These stimuli were then used subsequently in VSDI experiments. The properties of the observed VSDI responses

were largely consistent with the model’s predictions, suggesting that population gain control is a general mechanism for visual processing.

A second class of stimuli, consisting of a small Gabor element on top of a large Gabor background, was also studied in Chapter 6. The model predicted that linearity of the interaction would change systematically as the contrasts of the two Gabors vary. A specific physiological experiment was proposed to verify this prediction. This result demonstrates one key advantage of computational models: It is possible to sample many different features of the stimulus to discover systematic changes.

The model’s responses for these two classes of stimuli were then used to predict how the interaction can affect perception, providing insight on how neural responses may be decoded in the brain.

In Chapter 7, the PGC model was applied to moving stimuli. Such stimuli constitute a challenging test for the generality of the model, which was based on the observations in the responses of small stationary stimuli only. The model predicted that the responses in a movie would have a shorter latency than a stationary wedge at the same location. The relative latency between these two conditions was predicted to increase in locations along the wedge’s motion and to be limited by the receptive field sizes. These predictions were consistent with the VSDI responses of such stimuli. Specifically, the values of the relative latencies at different locations for the full movies and their cut versions agreed with the model’s predictions, suggesting that it is a general, accurate, yet simple model for population responses in the visual cortex.

## 9.2 Conclusion

PGC is a new model for large neural populations that takes into account the dynamics of the responses. It provides a promising foundation for further research on neural computation at the population level in other cortical areas. Different interconnected areas can also potentially be simulated by cascading the PGC models to study their interactions. Eventually, a complete functional pathway may be simulated accurately using PGC models, thus advancing our understanding of large-scale neural computation in a way that cannot be achieved by low-level biophysical models.

This dissertation shows that the complete spatiotemporal dynamics of large neural populations can be specified by a single PGC equation. The premise of this equation is the simple idea of gain control by response pooling, which can be implemented through the vast network in the brain. The results in this dissertation therefore suggest that not only is there a general principle for neural processing in the complex network of the brain, but it is a simple one as well.

# Vita

Yiu Fai Sit was born in Hong Kong to Kai Choi Sit and May Chu Jim. He graduated from Diocesan Boys' School in 1996. He then attended the University of Hong Kong, where he received B.Eng. in Computer Engineering with First-Class Honors in 2000 and M.Phil. in Computer Science in 2003. Then he left Hong Kong for Austin, TX to study at The University of Texas at Austin.
