Abstract

We describe some of our recent efforts in learning statistical models of co-occurring events from large text corpora using Recurrent Neural Networks.

1 Introduction

Natural language scripts are structured models of stereotypical sequences of events used for document understanding. For example, a script model may encode the information that from Smith landed in Beijing, one may presumably infer Smith flew in an airplane to Beijing, Smith got off the plane at the Beijing airport, etc. The world knowledge encoded in such event co-occurrence models is intuitively useful for a number of semantic tasks, including Question Answering, Coreference Resolution, Discourse Parsing, and Semantic Role Labeling.

Script learning and inference date back to AI research from the 1970s, in particular the seminal work of Schank and Abelson (1977). In this work, events are formalized as quite complex hand-encoded structures, and the structures encoding event co-occurrence are non-statistical and handcrafted based on appeals to the intuitions of the knowledge engineer. Mooney and DeJong (1985) give an early non-statistical method of automatically inducing models of co-occurring events from documents, but their methods are non-statistical.

There is a growing body of more recent work investigating methods of learning statistical models of event sequences from large corpora of raw text. These methods admit scaling models up to be much larger than hand-engineered ones, while being more robust to noise than automatically learned non-statistical models. Chambers and Jurafsky (2008) describe a statistical co-occurrence model of (verb, dependency) pair events that is trained on a large corpus of documents and can be used to infer implicit events from text. A number of other systems following similar paradigm have also been proposed (Chambers and Jurafsky, 2009; Jans et al., 2012; Rudinger et al., 2015). These approaches achieve generalizability and computational tractability on large corpora, but do so at the expense of decreased representational complexity: in place of the rich event structures found in Schank and Abelson (1977), these systems model and infer structurally simpler events.

In this extended abstract, we will briefly summarize a number of statistical script-related systems we have described in previous publications (Pichotta and Mooney, 2016a; Pichotta and Mooney, 2016b), place them within the broader context of related research, and remark on future directions for research.

2 Methods and results

In Pichotta and Mooney (2016a), we present a system that uses Long Short-Term Memory (LSTM) Recurrent Neural Nets (RNNs) (Hochreiter and Schmidhuber, 1997) to model sequences of events. In this work, events are defined to be verbs with information about their syntactic arguments (either the noun identity of the head of an NP phrase relating to the verb, the entity identity according to a coreference resolution engine, or both). For example, the sentence Smith got off the plane at the Beijing air-
port would be represented as (get off, smith, plane, (at, airport)). This event representation was investigated in Pichotta and Mooney (2014) in the context of count-based co-occurrence models. Balasubramanian et al. (2013), Modi and Titov (2014), and Granroth-Wilding and Clark (2016) describe systems for related tasks with similar event formulations.

In Pichotta and Mooney (2016a), we train an RNN sequence model by inputting one component of an event tuple at each timestep, representing sequences of events as sequences of event components. Standard methods for learning RNN sequence models are applied to learning statistical models of sequences of event components. To infer probable unobserved events from documents, we input observed document events in sequence, one event component per timestep, and then search over the components of a next event to be inferred using a beam search. That is, the structured prediction problem of event inference is reduced to searching over probable RNN output sequences. This is similar in spirit to a number of recent systems using RNN models for structured prediction (Vinyals et al., 2015; Luong et al., 2016; Dong and Lapata, 2016).

While the count-based event co-occurrence system we investigated in Pichotta and Mooney (2014) treats events as atomic—for example, the plane flew and the plane flew over land are unrelated events with completely independent statistics—this method decomposes events into components, and the two occurrences of the verb flew in the above examples have the same representation. Further, a low-dimensional embedding is learned for every event component, so flew and soared can get similar representations, allowing for generalization beyond the lexical level. Given the combinatorial number of event types, decomposing structured events into components, rather than treating them as atomic, is crucial to scaling up the number of events a script system is capable of inferring. In fact, the system presented in Pichotta and Mooney (2014) does not use noun information about event arguments for this reason, instead using only coreference-based entity information.

Table 1: Next event prediction results in Pichotta and Mooney (2016a). Partial credit is out of 1, and human evaluations are out of 5 (higher is better for both). More results can be found in the paper.

Table 1 gives results comparing a naive baseline (“Unigram,” which always deterministically guesses the most common events), a co-occurrence based baseline (“Bigram,” similar to the system of Pichotta and Mooney (2014)) and the LSTM system. The metric “Recall at 25” holds an event out from a test document and judges a system by its recall of the gold-standard event in its list of top 25 inferences. The “Human” metric is average crowdsourced judgments of inferences on a scale from 0 to 5, with some post hoc quality-control filtering applied. The LSTM system outperforms the other systems. More results and details can be found in Pichotta and Mooney (2016a).

These results indicate that RNN sequence models can be fruitfully applied to the task of predicting held-out events from text, by modeling and inferring events comprising a subset of the document’s syntactic dependency structure. This naturally raises the question of to what extent, within the current regime of event-inferring systems trained on documents, explicit syntactic dependencies are necessary as a mediating representation. In Pichotta and Mooney (2016b), we compare event RNN models, of the sort described above, with RNN models that operate at the raw text level. In particular, we investigate the performance of a text-level sentence encoder/decoder similar to the skip-thought system of Kiros et al. (2015) on the task. In this setup, during inference, instead of encoding events and decoding events, we encode raw text, decode raw text, and then parse inferred text to get its dependency structure. This system does not obviously encode event co-occurrence structure in the way that the

---

1With a vocabulary of $V$ verb types, $N$ noun types, $P$ preposition types, and event tuples of arity $k$, there are about $V^P N^{k-1}$ event types. For $V = N = 10000$, $P = 50$, and $k = 4$, this is $5 \times 10^{17}$.

2We use the Stanford dependency parser (Socher et al., 2013).
previous one does, but can still in principle infer
implicit events from text, and does not require a parser
(and can be therefore be used for low-resource lan-
guages).

Table 2: Prediction results in Pichotta and Mooney (2016b).
More results can be found in the paper.

Table 2 gives a subset of results from Pichotta and Mooney (2016b), comparing an event LSTM with
a text LSTM. The “Copy/paste” baseline determin-
istically predicts a sentence as its own successor. The “Accuracy” metric measures what percentage of
argmax inferences were equal to the gold-standard
held-out event. The “BLEU” column gives BLEU
scores (Papineni et al., 2002) for raw text inferred
by systems (either directly, or via an intermediate
text-generation step in the case of the Event LSTM
output). The “1G P” column gives unigram preci-
sion against the gold standard, which is one of the
components of BLEU. Figure 1, reproduced from
Pichotta and Mooney (2016b), gives some example
next-sentence predictions. Despite the fact that it is
very difficult to predict the next sentence in natural
text, the text-level encoder/decoder system is capa-
bale of learning learning some aspects of event co-
occurrence structure in documents.

These results indicate that modeling text directly
does not appear to appreciably harm the ability to
infer held-out events, and greatly helps in inferring
held-out text describing those events.

3 Related Work

There are a number of related lines of research inves-
tigating different approaches to statistically model-
ing event co-occurrence. There is, first of all, a body
of work investigating systems which infer events
from text (including the above work). Chambers and
Jurafsky (2008) give a method of modeling and in-
ferring simple (verb, dependency) pair-events. Jans
et al. (2012) describe a model of the same sorts of
events which gives superior performance on the task
of held-out event prediction; Rudinger et al. (2015)
follow this line of inquiry, concluding that the task
of inferring held-out (verb, dependency) pairs from
documents is best handled as a language modeling
task.

Second, there is a body of work focusing on au-
tomatically inducing structured collections of events
(Chambers, 2013; Cheung et al., 2013; Nguyen et
al., 2015; Ferraro and Van Durme, 2016), typically
motivated by Information Extraction tasks.

Third, there is a body of work investigating high-
precision models of situations as they occur in the
world (as opposed to how they are described in text)
from smaller corpora of event sequences (Regneri et
al., 2010; Li et al., 2012; Frermann et al., 2014; Orr
et al., 2014).

Fourth, there is a recent body of work investigat-
ging the automatic induction of event structure in
different modalities. Kim and Xing (2014) give a
method of modeling sequences of images from or-
dered photo collections on the web, allowing them to
perform, among other things, sequential image pre-
diction. Huang et al. (2016) describe a new dataset
of photos in temporal sequence scraped from web
albums, along with crowdsourced story-like descrip-
tions of the sequences (and methods for automati-
cally generating the latter from the former). Bosse-
lut et al. (2016) describe a system which learns a
model of prototypical event co-occurrence from on-
line photo albums with their natural language cap-
tions. Incorporating learned event co-occurrence
structure from large-scale natural datasets of differ-
ent modalities could be an exciting line of future re-
search.

Finally, there are a number of alternative ways
of evaluating learned script models that have been
proposed. Motivated by the shortcomings of eval-
uation via held-out event inference, Mostafazadeh
et al. (2016) recently introduced a corpus of crowd-
sourced short stories with plausible “impostor” end-
ings alongside the real endings; script systems
can be evaluated on this corpus by their ability
to discriminate the real ending from the impostor
one. This corpus is not large enough to train a
script system, but can be used to evaluate a pre-
trained one. Hard coreference resolution problems
(so-called “Winograd schema challenge” problems
(Rahman and Ng, 2012)) provide another possible
### 4 Future Work and Conclusion

The methods described above were motivated by the utility of event inferences based on world knowledge, but, in order to leverage large text corpora, actually model documents rather than scenarios in the world *per se*. That is, this work operates under the assumption that modeling event sequences in documents is a useful proxy for modeling event sequences in the world. As mentioned in Section 3, incorporating information from multiple modalities is one possible approach to bridging this gap. Incorporating learned script systems into other useful extrinsic evaluations, for example coreference resolution or question-answering, is another.

For the task of inferring verbs and arguments explicitly present in documents, as presented above, we have described some evidence that, in the context of standard RNN training setups, modeling raw text yields fairly comparable performance to explicitly modeling syntactically mediated events. The extent to which this is true for other extrinsic tasks is an empirical issue that we are currently exploring. Further, the extent to which representations of more complex event properties (such as those hand-encoded in Schank and Abelson (1977)) can be learned automatically (or happen to be encoded in the learned embeddings and dynamics of neural script models) is an open question.
