Interactively Shaping Agents via Human Reinforcement

The TAMER Framework

ABSTRACT
As computational learning agents move into domains that incur real costs (e.g., autonomous driving or financial investment), it will be necessary to learn good policies without numerous high-cost learning trials. One promising approach to reducing sample complexity of learning a task is knowledge transfer from humans to agents. Ideally, methods of transfer should be accessible to anyone with task knowledge, regardless of that person’s expertise in programming and AI. This paper focuses on allowing a human trainer to interactively shape an agent’s policy via reinforcement signals. Specifically, the paper introduces “Training an Agent Manually via Evaluative Reinforcement,” or TAMER, a framework that enables such shaping. Differing from previous approaches to interactive shaping, a TAMER agent models the human’s reinforcement and exploits its model by choosing actions expected to be most highly reinforced. Results from two domains demonstrate that lay users can train TAMER agents without defining an environmental reward function (as in an MDP) and indicate that human training within the TAMER framework can reduce sample complexity over autonomous learning algorithms.

Categories and Subject Descriptors: I.2.8 [Problem Solving, Control Methods, and Search]

General Terms: Algorithms, Human Factors, Performance

Keywords: human-agent interaction, shaping, sequential decision-making, human teachers, learning agents

1. INTRODUCTION
As computational learning agents continue to improve their ability to learn sequential decision-making tasks, a central but largely unfulfilled goal of the field is to deploy these agents in real-world domains, making decisions that affect our lives. However, with real-world deployment comes real-world costs. For such a deployment to be viable, agents will not be able to use hundreds or thousands of learning trials to reach a good policy when each suboptimal trial is costly. For example, an autonomous driving agent should not learn to drive by crashing into road barriers and endangering the lives of pedestrians.

Fortunately, for many of these tasks, humans have domain knowledge that could speed the learning process, reducing costly sample complexity. Currently, most knowledge transfer from humans to agents occurs via programming, which is time-consuming and inaccessible to the general public. It is important to develop agents that can learn from natural methods of communication. The teaching technique of shaping is one such method. In this context, we define shaping as interactively training an agent through signals of positive and negative reinforcement. In a shaping scenario, a human trainer observes an agent and reinforces its behavior through push-buttons, spoken word (“yes” or “no”), or any other signal that can be converted to a scalar signal of approval or disapproval. The key challenge, then, is to create agents that can be shaped effectively. Our problem definition is as follows:

The Shaping problem Within a sequential decision-making task, an agent receives a sequence of state descriptions \( (s_1, s_2, ..., s_t, s) \) and action opportunities (choosing \( a \in A \) at each \( s_t \)). From a human trainer who observes the agent and understands a predefined performance metric, the agent also receives occasional positive and negative scalar reinforcement signals \( r_1, r_2, ..., r_n \) that are correlated with the trainer’s assessment of re-

---

1 We use the term “shaping” as it is used in animal learning literature (in which it was initially developed by B.F. Skinner). There, shaping is defined as training by reinforcing successively improving approximations of the target behavior [6]. In reinforcement learning literature, it is sometimes used as in animal learning, but more often “shaping” is restricted to methods that combine the shaping reinforcement signal and the reward signal of the environment into a single signal [14]. An important feature of our TAMER framework is that the two signals are not combined.
cent state-action pairs. How can an agent learn the best possible task policy \((\pi : S \rightarrow A)\), as measured by the performance metric, given the information contained in the input?

In a Markov Decision Process (MDP), the environmental reward signal, along with the rest of the MDP specification (see [16] for details), unambiguously define a set of optimal policies. Since our goal is to allow the human trainer to fully control the agent’s behavior, the environmental reward signal is not used. Following Abbeel and Ng’s terminology [1], we call this an MDP\[R\].

Expected benefits of learning from human reinforcement\(^2\) include the following.

1. Shaping decreases sample complexity for learning a “good” policy.
2. An agent can learn in the absence of a coded evaluation function (e.g., an environmental reward function).
3. The simple mode of communication allows lay users to teach agents the policies which they prefer, even changing the desired policy if they choose.
4. Shaped agents can learn in more complex domains than autonomous learning allows.

This paper addresses the first three of these benefits. In it, we review previous work on agents that can learn from a human teacher through natural methods of communication (Section 2). We treat shaping as a specific mode of knowledge transfer, distinct from (and probably complementary to) other natural methods of communication, including programming by demonstration and giving advice. Shaping only requires that a person can observe the agent’s behavior, judge its quality, and send a feedback signal that can be mapped to a scalar value (e.g., by button press or verbal feedback of “good” and “bad”). We then present a novel method by which human trainers can shape agents (Section 3). This agent-trainer framework, called Training an Agent Manually via Evaluative Reinforcement (TAMER), makes use of established supervised learning techniques to model a human’s reinforcement function and then uses the learned model to choose actions that are projected to receive the most reinforcement.

The TAPER framework, the insights that motivate it, and an extension to delayed reinforcement are the key contributions of this paper. Furthermore, we describe two specific, fully implemented TAMER algorithms that provide proofs-of-concept for two contrasting task domains (Section 4). Experimental results in these domains show that TAMER agents, under the tutelage of human trainers, learn a “good” policy faster than effective autonomous learning agents (Section 5).

\(^2\)In this paper, we distinguish between human reinforcement and environmental reward within an Markov Decision Process. To avoid confusion, human feedback is always called “reinforcement.”

2. RELATED WORK: LEARNING FROM A HUMAN

Work on human-teachable agents has taken many forms, all with the aim of reducing the amount of programming required by an expert, using more natural modes of communication. In this section, we describe past work on agents that learn from humans. We argue that the relative strengths and weaknesses of our training system put it in a unique space that is not currently occupied by any other approach. Furthermore, we believe that many of the approaches we review are complementary to ours: an ideal learning agent might combine elements from several of them.

2.1 Learning from Advice

Advice, in the context of Markov Decision Processes (MDPs), is defined as suggesting an action when a certain condition is true. Maclin and Shavlik [12] pioneered the approach of giving advice to reinforcement learners. Giving advice via natural language could be an effective way for non-technical humans to teach agents. Kuhlmann et al. [11] created a domain-specific natural language interface for giving advice to a reinforcement learner.

The informational richness of advice is clearly powerful, however there still remain a number of technical challenges. The first of these is that general natural language recognition is unsolved, so many current advice-taking systems [12, 13] require that the human encode her advice into a scripting or programming language, making it inaccessible to non-technical users. The natural language unit of Kuhlmann et al. [11] required manually labeled training samples. Moreover, work still remains on how to embed advice into agents that learn from experience.

Additionally, there will likely be times when the trainer knows that the agent has performed well or poorly, but cannot determine exactly why. In these cases, advice will be much more difficult to give than positive or negative feedback.

2.2 Learning from Demonstration

Another way for a human to teach an agent is to demonstrate a task via remote-control or with his own body, while the agent records state-action pairs, from which it learns a general policy for the task [3].

In Apprenticeship Learning [1], a type of learning from demonstration, the algorithm begins with an MDP\[R\] (as does the TAMER framework: see Section 1). The algorithm learns a reward function \(R\) from a human’s period of control, and then the agent trains on the MDP.

Considering the demonstration type in which a human controls the agent, there are some tasks that are too difficult for a human trainer. This might be because the agent has more actuators than can be put in a simple interface (e.g., many robots) or because the task requires that the human be an expert before being able
to control the agent (e.g., helicopter piloting in simulation). In these cases, a demonstration is infeasible. But as long as the human can judge the overall quality of the agent’s behavior, then he or she should be able to provide feedback via TAMER regardless of the task’s difficulty.

2.3 Learning from Reinforcement (Shaping)
Within the context of human-teachable agents, a human trainer shapes an agent by reinforcing successively improving approximations of the target behavior. When the trainer can only give positive reinforcements, this method is sometimes called clicker training, which comes from a form of animal training in which an audible clicking device is previously associated with reinforcement and then used as a reinforcement signal itself to train the animal.

Previous work on clicker training has involved teaching tricks to entertainment agents. Kaplan et al. [9] and Blumberg et al. [4] implement clicker training on robotic and simulated dogs, respectively. Blumberg et al.’s system is especially interesting, allowing the dog to learn multi-action sequences and associate them with verbal cues. Though significant in that they are novel techniques of teaching pose sequences to their respective platforms, neither is evaluated using an explicit performance metric, and it remains unclear if and how these methods can be generalized to other, possibly more complex MDP settings.

Thomaz & Breazeal [18] interfaced a human trainer with a table-based Q-learning agent in a virtual kitchen environment. Their agent seeks to maximize its discounted total reward, which for any time step is the sum of human reinforcement and environmental reward.3

In another example of mixing human reinforcement with on-going reinforcement learning, Isbell et al. [8] enable a social software agent, Cobot, to learn to model human preferences in LambdaMOO. Cobot “uses reinforcement learning to proactively take action in this complex social environment, and adapts his behavior based on multiple sources of human [reinforcement].” Like Thomaz and Breazeal, the agent doesn’t explicitly learn to model the human reinforcement function, but rather uses the human reinforcement as a reward signal in a standard RL framework.

The TAMER system is distinct from previous work on human-delivered reinforcement in that it is designed both for a human-agent team and to work in complex domains through function approximation, generalizing to unseen states. It also uniquely forms a model of the human trainer’s intentional reinforcement, which it exploits for action selection in the presence or absence of the human trainer.

3. THE TAMER FRAMEWORK
Consider the Shaping problem description given in Section 1. The agent’s role is by nature somewhat underconstrained: it must learn from reinforcement such that it maximizes performance (which it cannot measure). We hypothesize that the agent best fills its role by learning a model of the trainer’s reinforcement and exploiting the model in action selection.

A TAMER agent seeks to learn the human trainer’s reinforcement function $H : S \times A \rightarrow \mathbb{R}$. Presented with a state $s$, the agent consults its learned model $H$ and, if choosing greedily, takes the action $a$ that maximizes $H(s, a)$. Figure 1 shows interaction between a human, the environment, and a TAMER agent within an MDP. Since the agent seeks only to maximize human reinforcement, the optimal policy is defined solely by the trainer, who could choose to train the agent to perform any behavior that its model can represent. When the agent’s performance is evaluated using an objective metric, we expect its performance to be limited by the information provided by the teacher.

3.1 Motivating Insights
When we speak of autonomous learning agents, we mean those that receive feedback in the form of environmental reward (i.e., reinforcement learning agents [16]). The principal challenge for such agents is, upon receiving environmental reward, to assign credit from that reward to the entire history of past state-action pairs. In domains where the only discriminating reward is at the end of the task, assigning this credit can be particularly difficult. A key insight of the TAMER framework is that the problem of credit assignment inherent in reinforcement learning is no longer present with an attentive human trainer. The trainer can evaluate an action or short sequence of actions, considering the long-term effects of each, and deliver positive or negative feedback within a small temporal window after the behavior. Assigning credit within that window presents a challenge in itself, which we discuss in Section 3.3, but it is much easier than assigning credit for an arbitrarily delayed re-

![Figure 1: Framework for Training an Agent Manually via Evaluative Reinforcement (TAMER).](image-url)
ward signal as in reinforcement learning. Assuming, for
now, that credit is properly assigned within the tempo-
ral window, we assert that a trainer can directly label
behavior. Therefore, modeling the trainer’s reinforce-
ment function $H$ is a supervised learning problem.

Intuition and some evidence [8] suggest that a human
trainer’s reinforcement function, $H$, is a moving target.
Intuitively, it seems likely that a human trainer will
raise his or her standards as the agent’s policy improves,
effectively more to get the same reinforcement. Though
we have not experimentally studied this claim that a
human’s reinforcement function is a moving target, it
is discussed in further detail in [10]. Considering our
conjecture that $H$ is a moving target function and that
the TAMER agent should be able to exploit new data as
it becomes available, the supervised learning algorithm
should both be able to handle changes in the target
function and allow incremental updates. Additionally,
for best results, the algorithm should generalize to all
unseen samples (i.e., to states and possibly actions).
Examples of such algorithms include gradient descent
over the weights of a linear model (which we use in
our experiments) and backpropagation in a multi-layer
neural network.

As we will report in Section 5, compared to autonomous
learning algorithms, TAMER dramatically reduces the
number of episodes required to learn a good policy. One
result of lowering the sample complexity is that if the
incremental updates to the model use a small step size,
the model’s output will not move far enough to ever be
the “true” human reinforcement function. But ideally
the learned function $\hat{H}$ should map to the human
reinforcement function $H$ such that

$$\hat{H}(s,a_1) > \hat{H}(s,a_2) \iff H(s,a_1) > H(s,a_2).$$

In this case, the policies created by greedily exploiting
$\hat{H}$ and $H$ are equivalent.

### 3.1.1 Exploration

The TAMER framework is agnostic to exploration, leaving
action selection as a black box to be filled by the
agent designer. However, we have found that greedily
choosing the action that is expected to receive the
highest reinforcement provides sufficient exploration for
many tasks, including those described in Section 5. This
counterintuitive finding is easily justified. In a given
state, a good trainer negatively reinforces any undesired
action, eventually dropping its expected reinforcement
below another action, resulting in a new (exploratory)
action choice. A non-greedy action selection method
is needed if there are actions of which the trainer is
not aware or does not know the value. Otherwise, the
trainer should be able to guide the TAMER agent’s ex-
ploration sufficiently under greedy action selection.

---

### Algorithm 1 A general greedy TAMER algorithm

**Require:** Input: stepSize

1. ReinfModel.init(stepSize)
2. $s \gets \emptyset$
3. $f \gets \emptyset$
4. while true do
5.  $h \gets $ getHumanReinfSincePreviousTimeStep()
6.  if $h \neq 0$ then
7.    $error \gets h - ReinfModel.predictReinf(\hat{f})$
8.    ReinfModel.update($f$, error)
9.  end if
10. $s \gets $ getStateVec()
11. $a \gets \arg\max_a (\text{ReinfModel.predict}(\text{getFeatures}(s, a)))$
12. $f \gets $ getFeatures($s$, $a$)
13. takeAction($a$)
14. wait for next time step
15. end while

---

### 3.1.2 Comparison with Reinforcement Learning

The TAMER framework for shaping agents shares much
common ground with reinforcement learning, but there
are some key differences that are important to under-
stand in order to fully appreciate TAMER.

In reinforcement learning, agents seek to maximize re-
turn, which is a discounted sum of all future reward. In
contrast, a TAMER agent does not seek to maximize a
discounted sum of all future human reinforcement. In-
stead, it attempts to directly maximize the short-term
reinforcement given by the human trainer. It does this
because the trainer’s reinforcement signal is a direct la-
bel on recent state-action pairs.

Correspondingly, the human’s reinforcement function $H$
is not an exact replacement for a reward function $R$
within an MDP. Although it may be possible for a re-
forcement learning algorithm to use $H$ in lieu of a re-
ward function, it would be unnecessary extra computa-
tion, since $H$ already defines a policy. We use MDP\'s
because the environmental reward within MDPs func-
tion dictates the optimal policy, so $R$ is removed to
make the human’s reinforcement function the sole de-
terminant of good and bad behavior.

Many reinforcement learning algorithms can be easily
converted to TAMER algorithms. We encourage inter-
ested readers to follow our step-by-step instructions at

### 3.2 High-Level Algorithm

A high-level algorithm for implementing TAMER is de-
scribed in Algorithm 1. After initialization of the re-
forcement model $\text{ReinfModel}$, the state vector $s$, and
the feature vector $f$ (lines 1-3), the algorithm begins a
loop that occurs once per time step (line 4).

In the loop, the agent first obtains a scalar measurement
of the human trainer’s reinforcement since the previous
time step (line 5). If the reinforcement value is nonzero,
then the error is calculated as the difference between the
actual reinforcement and the amount predicted by
the agent’s reinforcement model (line 7). The model, left undefined for the general TAMER algorithm, can be instantiated in multiple ways as discussed below. The calculated error is then used, along with the previous feature vector, to update the reinforcement model (line 8). The update is not performed when $h = 0$ because the trainer may not be paying attention or might even have quit training altogether, satisfied with the trained policy.

After the agent obtains the new state description, it then greedily chooses the action $a$ that, according to the human reinforcement model, yields the largest predicted reinforcement (lines 10-11). Although we have found that greedy action selection is sufficient in our work thus far, more sophisticated action selection methods may be needed in some situations, and would fit just as well within the TAMER framework. The agent calculates features $\tilde{f}$ of the state and action of the current time step (line 12) and takes the chosen action (line 13) before restarting the loop.

### 3.3 Credit Assignment to a Dense State-Action History

In some task domains, the frequency of time steps is too high for human trainers to respond to specific state-action pairs before the next one occurs. In simulation, it is technically possible to lower the frequency of time steps. But doing so may change the character of the task, and in physical domains (e.g. helicopter flight) it may not be possible. Although we have not studied exactly where the frequency threshold is, our experience and studies of human response times (Figure 2) [7] have made it clear that having several seconds between time steps is enough for specific labeling and, conversely, having several time steps per second is too frequent for specific labeling.

For these faster domains, credit from the human’s reinforcement must be appropriately distributed across some subset of the previous time steps. Our approach for credit assignment with a linear model and gradient descent updates is shown in Algorithm 1, which is an extension of Algorithm 1 with the model inline. The error for an update is the difference between the model’s projected reinforcement, where the input is a weighted sum of the state-action features for each preceding time step (lines 9-13), and the actual reinforcement (line 14). The weight for any time step is its “credit”. The model is then updated with that error and the weighted sum of features (line 15).

![Figure 3: Probability density function $f(x)$ for a gamma(2.0, 0.28) distribution. Reinforcement signal $h$ is received at time 0. If $t$ and $t'$ are times of consecutive time steps, credit for the time step at $t$ is $\int_{t'}^t f(x)dx$. Note that time moves backwards as one moves right along the x-axis.](image)

#### 3.3.1 Credit Calculation

To assign credit, we assume that the reinforcement signal (received at time 0) is targeting a single state-action pair. This assumption will undoubtedly be wrong at times, but the effects of the assumption will probably be small since the credit is still spread out amongst recent events, as described below. There are $n$ time steps that might be the target, beginning at times $t_1, t_2, ..., t_n$, where $i < j$, then $t_i$ occurred more recently than $t_j$. (Therefore the time step beginning at $t_i$ ends at time $t_{i-1}$ if $i > 1$.) We define credit $c_i$ for a time step starting at time $t_i$ and ending at $t_{i-1}$ (or 0 if $i = 1$) to be the probability that the reinforcement signal was given for the event $(s, a)$ that occurred during that time step.

We create a probability density function $f$ over the delay of the human’s reinforcement signal. Then for any state-action pair, credit is calculated as the integral of $f$ from $t_{i-1}$ to $t_i$.

\[
c_i = P(\text{event starting at } t_i \text{ was targeted}) \\
= P(\text{target event between } t_{i-1} \text{ and } t_i \text{ sec. ago}) \\
= \int_{t_{i-1}}^{t_i} f(x)dx
\]

(If $i = 1$, then $t_{i-1} = 0$ in the above equation.) We observe the constraint

\[
\sum_{i=1}^{n} P(\text{event starting at } t_i \text{ was targeted}) = 1
\]

An example probability density function is shown in Figure 3. In practice, we maintain a window of recent time steps, pruning out those time steps that are older and have near-zero probability (lines 10 and 21). We also always use functions that have zero probability before 0.2 seconds, assuming that human trainers cannot respond in less than 0.2 seconds (supported by Figure 2).

### 4. IMPLEMENTED ALGORITHMS

TAMER is fully implemented and tested in two contrasting domains. Though the TAMER agent actively seeks to
maximize predicted human reinforcement $H$, the true objective of the human-agent system is to maximize some performance criteria, whether it be the trainer’s subjective evaluation or an explicitly defined metric. For this reason, and because measuring directly against $H$ is impractical to impossible, we evaluate TAMER using $R$ to provide the performance metric, which is the cumulative MDP reward received throughout all episodes in a run. In each domain, $R$ (ignored by the agent) was easily communicated to the trainer, who was instructed to train his or her agent to earn the highest sum of environmental reward per trial episode.6 Also, in each domain the state and action are displayed graphically to the human trainer. Both task domains were implemented within the RL-Library.7 One domain is Tetris, a puzzle computer game with a large state space and a variable number of actions per time step (as is standard in the literature, a final placement of a falling Tetris piece is considered an action). The time step frequency in Tetris, at less than one action per second, allowed human trainers to easily reinforce individual actions. Also, agents started each episode in a random location within bounds around the bottom of the hill.

These two domains complement each other. Tetris has a complex state-action space and low time step frequency, and Mountain Car is simpler but occurs at a high frequency.

4.1 Tetris

The algorithm used to implement TAMER on Tetris is a specific implementation of Algorithm 1, using a linear model and gradient descent over the weights of each feature. The function $getFeatures(\vec{s}, a)$ on line 13 of the algorithm considers feature vectors derived from both the current state and the next state (before the new Tetris piece appears). The next state is merely the previous state with the new blocks in place (which the action dictates) with any full horizontal lines removed. The difference between the two feature vectors is returned and actually used by TAMER as the features over which to learn.

4.2 Mountain Car

The Mountain Car TAMER algorithm follows the algorithm given for TAMER with credit assignment described in Algorithm 2, also using a linear model with gradient descent updates. The function $getFeatureVec(\vec{s}, a)$ on lines 19 and 20 is implemented using 2-dimensional Gaussian radial basis functions as described in [16]. Credit assignment followed a Uniform(0.2, 0.6) distribution (described in more detail in Section 3.3).

5. RESULTS AND DISCUSSION

Our experiments test the first three of the the expected benefits of shaping that are described in the Introduction: shaping decreases sample complexity for learning a "good" policy, an agent can learn in the absence of a coded evaluation function, and lay users can teach agents the policies they prefer. For the experiments, human trainers observed the agents in simulation on a computer screen. Positive and negative reinforcement was given via two keys on the keyboard. The trainers were read instructions and were not told anything about the agent’s features or learning algorithm. Nine humans trained Tetris agents. Nineteen trained Mountain Car agents. For each task, at least a fourth of the trainers did not know how to program a computer.

5.1 Tetris

Tetris is notoriously difficult for temporal difference learning methods that model a function such as a value or action-value function. In our own work, we were only able to get Sarsa(\(\lambda\)) [16] to clear approximately 30 lines per game with a very small step size \(\alpha\) and after hundreds of games. Bertsekas and Tsitsiklis report that they were unable to get optimistic TD(\(\lambda\)) to make "substantial progress". RRL-KBR [15] does somewhat better, getting to 50 lines per game after 120 games or

---

6Our Tetris specification follows that described by Bertsekas and Tsitsiklis [2]. Experimental details and videos of agents before, during, and after training can be found at http://www.cs.utexas.edu/users/bradknoxx/kcap09.

7http://code.google.com/p/rl-library/
The only successful approach that learns a value function (of those found by the authors) is λ-policy iteration [2], which reaches several thousand lines after approximately 50 games.

However, λ-policy iteration differs in two important ways from the rest of these value-based approaches. First, it begins with hand-coded weights that already achieve about 30 lines per game. Getting to that level of play is nontrivial, and some learning algorithms, such as Sarsa(λ), fail to even reach it when starting with all weights initialized to zero. Second, λ-policy iteration gathers many state transitions from 5 games and performs a least-squares batch update. All other successful learning methods likewise perform batch updates after observing a policy for many games (as many as 500 in the best-performing algorithms), likely because of the high stochasticity of Tetris. Additionally, of those that have the necessary data available, all previous algorithms that model a function are unstable after reaching peak performance, unlearning substantially until they clear less than half as many lines as their peak.

In our experiments, human trainers practiced for two runs. Data from the third run is reported. Of the algorithms that model an actual function, our gradient descent, lineariser TAMER is the only one that clearly does not unlearn in Tetris. Of those that also perform incremental updates, TAMER learns the fastest and to the highest final performance, reaching 65.89 lines per game by the third game (Table 1 and Figure 4).

Policy search algorithms, which do not model a value or reinforcement function, attain the best final performance, reaching hundreds of thousands of lines per game [5, 17], though they require many games to get there and do not learn within the first 500 games.

Within our analysis, TAMER agents learn much more quickly than all previously reported agents and reach a final performance that is higher than all other incrementally updating algorithms.

5.2 Mountain Car

We should note that Ramon et al. rejected a form of their algorithm that reached about 42 lines cleared on the third game. They deemed it unsatisfactory because it unlearned by the fifth game and never improved again, eventually performing worse than randomly. Ramon et al.’s agent is the only one we found that approaches the performance of our system after 3 games.

This statement is supported by training by one of the authors but not necessarily by the subjects, since the trainer subjects usually stopped training after the TAMER agent reached satisfactory performance.

Most trainers stopped giving feedback by the end of the fifth game, stating that they did not think they could train the agent to play any better. Therefore most agents are operating with a static policy by the sixth game. Score variations come from the stochasticity inherent in Tetris, including the highest scoring game of all trainers (800 lines cleared), which noticeably brings the average score of game 9 above that of the other games.

![Mean Reward By Group in Tetris](image)

The Tetris results demonstrate TAMER’s effectiveness in a domain with relatively infrequent actions. Conversely, our experiments in Mountain Car test its performance in a domain with frequent actions. The autonomous algorithm used for comparison was Sarsa(λ) [16] with the same function approximator (a linear model over Gaussian RBF features, using gradient descent updates), an algorithm that is known to perform well on Mountain Car. Two Sarsa(λ) agents were used: one tuned for total cumulative environmental reward across all previous episodes (Figure 6) after 3 episodes and one tuned for after 20 episodes (which we will refer to as Sarsa-3 and Sarsa-20, respectively). We tuned via a hill-climbing algorithm that varied one parameter (α, λ, or ε in the standard notation of Sarsa [16]) at a time, testing the agent’s performance under each value for that parameter, taking the best performing value, and then repeating (for fifty or more iterations). The specific number of episodes (3 and 20) were chosen to exhibit different emphases on the trade-off between learning quickly and reaching the best asymptotic performance.

The TAMER agents were shaped for three runs of twenty episodes by each trainer. We consider the first run a practice run for the trainer and present the combined data from second and third runs. Results are shown in Figures 5 and 6. Figure 5(a) shows that the TAMER agents, on average, consistently outperformed the Sarsa-3 agent and outperformed the Sarsa-20 for the first five episodes, after which Sarsa-20 agents showed comparable performance. Under the guidance of the best trainers (Figure 5(b)), TAMER agents consistently outperform any Sarsa agent, and, under the worst trainers, they perform somewhat worse than the Sarsa-20
6. CONCLUSION AND FUTURE WORK

The TAMER framework, which allows human trainers to shape agents via positive and negative reinforcement, provides an easy-to-implement technique that:

1. works in the absence of an environmental reward function,
2. reduces sample complexity, and
3. is accessible to people who lack knowledge of computer science.

Our experimental data suggests that TAMER agents outperform autonomous learning agents in the short-term, arriving at a “good” policy after very few learning trials. It also suggests that well-tuned autonomous agents are better at maximizing final, peak performance after many more trials.

Given this difference in strengths, we aim to explore how best to use both human reinforcement, $H$, and, when available, environmental reward, $R$, relying on the former more heavily for early learning and on the latter for fine-tuning to achieve better results than either method can achieve in isolation. We would also like to implement TAMER in tasks that are currently intractable for autonomous learning algorithms. Further, we wish to investigate how TAMER might need to be modified for tasks in which a trainer cannot evaluate behavior within a small temporal window (e.g., the behavior is hidden at times or the results of the behavior are delayed).
