GATEway: Symbiotic Inter-Domain Traffic Engineering

the date of receipt and acceptance should be inserted later

Abstract There are a group of problems in networking that can most naturally be described as optimization problems (network design, traffic engineering, etc.). There has been a great deal of research devoted to solving these problems, but this research has been concentrated on intra-domain problems where one network operator has complete information and control. An emerging field is inter-domain engineering, for instance, traffic engineering between large autonomous networks. Extending intra-domain optimization techniques to inter-domain problems is often impossible without the information available within a domain, and providers are often unwilling to share such information.

This paper presents an alternative: we propose a method for traffic engineering that does not require sharing of important information across domains. The method extends the idea of genetic algorithms to allow symbiotic evolution between two parties. Both parties may improve their performance without revealing their data, other than what would be easily observed in any case. We show the method provides large reductions in network congestion, close to the optimal shortest path routing across a pair of networks. The results are highly robust to measurement noise, the method is very flexible, and it can be applied using existing routing.

1 Introduction

Optimization is the natural approach to many problems in networking. For instance: network design, traffic engineering, and routing are all optimization problems. We typically seek the solution that minimizes some (perhaps abstract) cost across the network in question.

However, there is no one authority which can perform such an optimization for "the Internet". The Internet is broken into many Autonomous Systems (ASes), each of which is managed independently, and these individual sub-networks are often unwilling to co-operate. Hence, many problems in networking are treated as game-theory problems with selfish participants, each trying to optimize for their own benefit alone. However, it has long been known [1] that selfish behaviors can result in poor outcomes.

However, network operators are not entirely "selfish". For instance current Internet routing relies on a certain amount of co-operation to ensure smooth operation — when networks don't connect properly, the first thing operators do is talk to each other on the phone. Their apparent unwillingness to co-operate arises frequently from an inability to share data that might reveal trade secrets, or violate privacy legislation. Without shared information, it seems we cannot jointly optimize more than one network, and so the participants are forced to a more selfish model.

This paper describes an approach based in part on the idea of privacy-preserving distributed computation. Such computation can be used to create methods for joint optimization between networks, without the type of "risky" co-operation that most previous methods of joint optimization require. We focus here on the inter-domain Traffic Engineering (TE) problem. In particular, our method is aimed at allowing TE to proceed without the providers sharing information that they consider private. This prevents the partners in the optimization exploiting information gained about its competitors, prevents gaming of the situation, and provides a basis for trust.

We exploit two key ideas: firstly, we use an optimization heuristic based on the metaphor of Darwinian evolution, commonly called a Genetic Algorithm (GA). GAs proceed

Table 1 Comparison of approaches. Communications cost for the privacy-maximization approach are a worst case, with the likely cost being significantly smaller. Performance is given in terms of average maximum utilization relative to the measured routing case (smaller percentages are better).

Approach	Shared data	Communications cost	Performance
joint SP	$\mathscr{G}_i$, $\mathbf{c}_i$, $\mathbf{w}_i$, D	$O(N^2+EK)$	46.6%
symbiotic	$\mathbf{q}_i$, $\max_{e\in E_i} u_e$	$O(GPN_{\max}\log Q)$	51.5%
symbiotic 2	$\mathbf{q}_i$,	$O(GPN_{\max}\log Q)$	68.4%
privacy-max	sel.prob.s $p(\mathbf{x}_i)$	$O(GPE^2N^2)$	51.5%
selfish	none	zero	91.2%

by describing the optimization variables using a series of "genes". A population is created, allowed to compete, and the most successful are allowed to reproduce. We call our approach *GATEway* (Genetic Algorithm Traffic Engineering). GAs are ideally suited to cases where the objective function is hard to compute, and we use this feature here by extending the metaphor to allow *symbiosis* between pairs of providers. In nature, symbiotic organisms jointly evolve, but they do not need to share genetic material to do so. Analogously, GATEway allows two providers to optimize their routing without sharing the details of their own networks (their genes). Despite this secrecy, we show that on Rocketfuel networks GATEway dramatically improves performance as compared to existing provider routing, and selfish routing procedures. In fact, GATEway provides results within 5% of a reasonable lower-bound on the possible performance, and about 40% better than the closest equivalent selfish routing.

As in biology, some information sharing is still required even in the above approach, primarily in the form of fitness functions. The fitness of each member of the population must be evaluated (in biology this would be implicit in whether individuals survive to breed). We then use techniques from the secure distributed computation community to substantially reduce even this modicum of information sharing. This allows the above optimization to be conducted without leaking any direct information about the providers, for instance, they do not need to share topology, link capacity, internal traffic, or routing details. In fact, in the strictest version of GATEway, the providers share almost no information at all, though there is a penalty to be paid for such parsimony. Ironically, despite sharing less information, the communication cost increases.

In more detail, we compare five alternative techniques for performing joint TE between several networks. All are based on shortest-path weight optimization techniques because of their simplicity, ease of implementation, and robustness [13,15]. As benchmarks we compare routing where each network optimizes its own routing selfishly, and routing where we treat the group of networks as a single large network over which we perform a joint shortest-paths optimization. Against these, we compare three new algorithms:

- **symbiotic:** the simple symbiotic approach outlines above.
- **symbiotic 2:** the symbiotic without shared fitness function calculation.
- **privacy-max:** a technique that exploits formal cryptographic techniques for privacy-preservation to minimize the amount of leaked information.

Table 1 summarizes the results, including the information that needs to be shared by each algorithm. The notation is defined later, but in summary, the joint approach requires sharing of all data (network topologies, link capacities, and internal traffic matrices though we assume that the inter-domain traffic matrices between a pair of network operators are measured by each participant). The selfish approach does not require any sharing of data, but its performance (91.2% on average) is poor compared to the joint approach. The first symbiotic algorithm requires that we share only our choices of egress points for traffic, and fitness calculations over a population of possible routing solutions. The resulting performance is 51.5%, which is very close to the joint approach. The fitness calculation carries relatively little information, but if we are concerned about this leakage then we can restrict transmission of fitness functions, but as noted this reduces the performance (to 68.4%). We also present an alternative method "privacy-max" which only needs to share selection probabilities across populations. This method therefore reduces information leakage, but this time the performance is good and the cost is that the communications overhead increases as N^2 (where N is the number of nodes in the joint network).

Applying symbiosis to GAs represents a new approach to secure distributed computation. Previously, many of the algorithms applied for secure distributed computation have been based on Yao's two-party protocol, which can compute any polynomial time function. We show here that we can find approximate solutions to NP-hard problems. The problem we consider here is quite specific, but there are many other fields where similar issues are encountered. Our approach is quite generic, and so may be applicable to other problems both in network engineering, and outside.

We further address some of the practical problems of using such a protocol. We demonstrate the flexibility of the approach by using alternative optimization objectives and showing performance improvements increase significantly with the number of networks using the method, and we also

find that the method is highly insensitive to measurement noise. The symbiotic methods also actually improves computation times in comparison to the joint algorithm. Additionally, we demonstrate that such an approach could be practically implemented in today's networks.

2 Background and Related work

2.1 Traffic Engineering

There are many tasks in network operations which fall under the heading of optimization. In this paper we shall concentrate on Traffic Engineering (TE), the process of balancing one's traffic across the existing links in a network. One may think of this as optimizing the routing parameters of a network, such that the resulting routing is "beneficial" in some sense. The routing parameters determine, for each source-destination pair, the fraction of traffic going on different paths from the source to the destination. Many TE techniques have been presented (for examples see [2–15]). The majority of the TE literature concerns intra-domain TE. That is, optimization of routing parameters within a single network. There are many approaches to this problem, though the two most prevalent are given below.

Explicit path where the traffic is arbitrarily routed to satisfy the results of a multi-commodity flow optimization [16, Chapter 17]. Explicit path routing is generally instantiated through MPLS (Multi-Protocol Label Switching) or IP-in-IP encapsulation [17].

Shortest-path where the routing uses shortest-paths, but the link weights are arbitrarily chosen as the result of some optimization. Shortest-path routing is appealing because it can be implemented easily using today's most commonly used Interior Gateway Protocols (IGPs) In these protocols each link is associated with a positive weight, and path length is defined as the sum of the weights of all the links on that path. Traffic is routed along the shortest paths. In cases of ties the flow is generally split (roughly evenly) across Multiple Equal-Cost Paths (MECP).

Explicit path optimization has less constraints, and therefore must achieve a superior solution to the shortest-path optimization. Naively, one supposes that explicit path optimization will perform significantly better. However, there is now substantial literature supporting shortest-path optimization. It has been shown that (for realistic networks) one can get within a few percent of the performance of explicit path routing [6], even where the inputs contain prediction or inference errors [13, 15]. What's more shortest-path optimization can choose sets of weights that perform well over a range of traffic (say the variations over the course of a day) [9, 15] or under link failures [14, 18, 19].

Either technique is appropriate within a single network, but both have flaws for inter-domain TE, a topic of recent interest [17, 20–28]. The Internet has a broad two-level hierarchy in its routing, separating intra-domain routing from inter-domain routing. BGPv4 (the Border Gateway Protocol version 4) is the de facto standard for inter-domain routing. When considering inter-domain routing, one must consider the interactions between IGP and BGP [29, 30]. Inter-domain MPLS solutions could in theory avoid some of the problems of interaction, but there are still practical complexities in using MPLS in inter-domain routing [26, 27]. Shortest-paths routing cannot be used because it might violate BGP policies. For example, peering agreements typically prohibit transit traffic (i.e. traffic that use backbone B to transit between two points on backbone A), but shortest-path routing allows transit.

There is another problem: traditional traffic engineering algorithms require complete topology and traffic information from all networks. ISPs are typically unwilling to share information such as their topology, link capacities, internal traffic volumes, and routing policies, particularly with potential competitors. As noted in [27] optimization methods which do not have complete information often fall short in performance. Similarly [31] shows that if ISPs co-operate in determining inter-domain routing they can achieve better performance. Can we still attain this improved performance if the ISPs will not share information? It is this problem that we concentrate on here. *How may we perform inter-domain traffic engineering without sharing detailed topological and traffic information?* This is the major difference between our work and the majority of the literature on TE.

The primary problem we consider here is a connected pair of ISPs who wish to optimize the routing of traffic on their joint network. We do not separate the problem into separate intra- and inter-domain TE problems, but regard the joint TE problem. The most closely related works to our own are [31, 32]. Our results agree completely with [31] in that ISPs may gain much larger benefits from TE if they cooperate. We attempt to go further in providing secrecy for the parties. In [31] the providers must reveal opaque preference classes per flow. These certainly hide a great deal of the internal information of a network, but still open the network to indirect inference about its properties if not very carefully implemented. We aim to show just how little information needs to be shared to perform a joint optimization, and the tradeoffs between sharing information and performance.

GATEway is pragmatic in the sense that we aim to solve the problem in a way implementable using current routing protocols without modification. The primary constraint this applies to our work is that we use BGP for inter-domain routing. BGP provides quite good means to control outgoing traffic, but only limited means to control an ISP's incoming traffic. However, if two network operators jointly control their outgoing traffic the effect is control in both directions. In [31] this is achieved through negotiation of the

exit points. We shall also aim to control exit points for traffic, though the choices will only be negotiated implicitly. We will refer to the type of routing solution we consider as *pinned-exit routing*, because the ISPs *pin* the exit point of particular flows. However, we will use shortest-path routing within an ISP, and we will not allow path sharing other than across MECPs.

Evolutionary algorithms have been applied in this context before [28], but that paper is concerned with quite a different issue, namely the fact that there can be multiple objectives when performing inter-domain TE. The paper searches for non-dominated fronts in order to describe characteristics of inter-domain routing, whereas we are looking for particular solutions to a single objective optimization problem.

2.2 Privacy Preserving Computation

The problem we consider comes under the heading of *secure distributed computation*, i.e. computing some function of several pieces of data without explicitly combining data (and thus revealing it). Another term used to describe this would be *privacy-preserving multiparty computation* (we use the terms synonymously).

The area of secure distributed computation has been heavily influenced by Yao's two party protocol [33,34], which is a protocol between two peers that can compute any polynomial-time function pair $(f_x(\mathbf{x},\mathbf{y}), f_y(\mathbf{x},\mathbf{y}))$, where $\mathbf{x}$ and $\mathbf{y}$ are the inputs and $f_X(\cdot)$ and $f_Y(\cdot)$ are the functions of interest to the two parties X and Y, respectively. The impressive thing about the protocol is that neither party learns the other's input data, or their output, i.e. X only learns f_X, not f_Y or $\mathbf{y}$. The classic example of Yao's protocol is the computation of the minimum of two values. The protocol requires two rounds of communication and has $O(n)$ computation and communication cost (where the numbers are represented in n bits). However, the protocol is not always efficient, and so many techniques have been developed to improve computational complexity and communications costs for specific problems. This area is now well developed – see [35] for a listing of a number of significant papers. Relatively little work has been done on privacy preserving computation for Internet applications. Brickell and Shmatikov [36] provide an algorithm to solve the shortest-paths through a pair of connected networks, and Machiraju and Katz [32] consider the flow maximization problem for a pair of networks. Note though that these both have polynomial time algorithms for the non-distributed problem. Yao's two party protocol, and related approaches provide methods for computing polynomial time functions. The problems here are NP hard.

Also importantly, note that in some problems, even though an algorithm leaks no side-information, X or Y might still derive information about the inputs from the output alone. A good example is the shortest-path problem: the privacy-preserving algorithm for shortest paths on a pair of connected networks is strictly privacy preserving [36]. However, knowledge of the output (shortest-paths) is sufficient to derive information about the weights of the joint network [37]. There is an important distinction between ensuring that the computation is private as opposed to the results being something that the two parties are willing for their partner to know.

On the other hand some of the input data may be easily observable by both parties in any case. For instance, in the shortest-path example when the routing is implemented we could simply measure it. Hence leakage of this information is inconsequential. Given these two features, we do not concern ourselves with strict privacy-preservation here. Instead, we seek to minimize the leakage (by the algorithm or solutions) of information that could not be otherwise observed by the participants. It is no longer a formal, provable definition (as is strict privacy-preservation) but it's consistent with the aims of potential participants in GATEway.

2.3 Assumptions

Most approaches to inter-domain traffic engineering can be characterized as selfish (where one provider acts unilaterally to improve its own performance), or as co-operative where the providers are willing to share information and co-operate (exceptions being [31, 32]). In GATEway we aim to get the best of both worlds. Note, we may still assume that the providers are selfish, but not in quite the same sense meant elsewhere. They will seek to maximize their own gains. However, in the approach we propose, we change the outcome of problems such as the Prisoner's Dilemma by introducing a type of trust. If the prisoners can trust each other, then they can achieve the global optimum. Note that both are still acting selfishly, but given the additional information, the correct selfish choice is also the global optimum.

The model we assume for network operators is sometimes called "semi-honest". It assumes that the providers are not malicious, i.e. they will not deliberately aim to cause damage other network operators, without any positive gain for themselves. They will not act like a "Dog in the Manger" (Aesop). Such participants are sometimes called "honest but curious", because they may seek to find out information, and exploit this information to their own benefit (and possibly to the detriment of other operators). This is a fair assumption because given BGP's current security limitations, the current Internet relies on honest participants.

2.4 GAs

The concept of a Genetic Algorithm (GA) (see [38] and the vast number of publication since) is based on the metaphor of Darwinian evolution — survival of the fittest. The idea, in brief, is to create a population of solutions to a problem, and then let them reproduce and evolve such that we tend to keep better solutions to the problem.

One key advantage of a GA is that the fitness need not be specified in closed form. For instance, GAs are often used in optimizing strategies for games where the fitness is determined by competition between the members of a population. This advantage is key in our application because it allows the parties involved in the computation to share only limited information about fitnesses, rather than the details of each others networks.

GAs may have the disadvantage that of being slow. Algorithms that are carefully tuned to the application in question often perform faster than GAs, particularly where large parameter spaces must be explored. However, the GA approach we develop has broadly similar performance to [6].

We extend the use of biological metaphors in GATEway to the use of the term *symbiosis*. In biology, symbiosis (sometimes mutualism) refers to two different organisms that form a mutually beneficial union. A classical example occurs in coral reefs [39]. Coral polyps are a small colonial organism that build large endo-skeletal reefs out of calcium carbonate. However, they get the majority of their food supply from photo-synthetic algae (zooxanthellae) which reside inside them, and incidentally provide them with their attractive coloration. The algae gain a safe home, while the coral polyps gain a food supply – both parties benefit from the interaction. Typically such organisms co-evolve to this state, i.e. both evolve together jointly (ancient corals did not exhibit this relationship). Co-evolution is not restricted to symbiotic relationships — it can also occur for competitors for instance — but the key is that the two organisms don't need to share genetic material to perform such a co-evolution. We exploit this in GATEway.

3 Evaluation Methodology

3.1 Test networks

We have tested GATEway on two sets of topology data. Random networks, and Rocketfuel networks. While we also use random networks to validate GATEway these tests are omitted, because they are consistent with and add little to the findings on more realistic topologies.

The Rocketfuel topologies [37] consist of a large number of networks and their peering links mapped primarily using traceroutes. The network maps produced are not perfect, however, they represent the best current maps showing both the intra-domain and inter-domain topologies of a significant number of large networks, and we avoid some of the problems in these network maps by considering the networks at the Points-of-Presence (PoP) level. We concentrate on a group of tier-1 networks, based primarily in North America (though some have significant components in Europe, Asia and the Pacific). We choose these because they all peer with each other with multiple physical connections. In addition, these networks are the largest, and thus provide the best test of the scalability of GATEway. The result is that we consider 7 networks, which each interconnect resulting in 21 possible pairs on which to trial the method. Additionally, there is little point in trying to optimize routing for degree one nodes (there is only one link they can use), and so we eliminate such nodes from the networks under consideration. The networks used are shown in Table 2, along with parameters such as the number of links and PoPs, which form the nodes in the graph.

Table 2 The Rocketfuel networks used in this study, listed by Autonomous System Number (ASN).

ASN	Name	PoPs (degree ≥ 2)	links
1	Genuity	24	74
701	UUNet	48	368
1239	Sprint	33	130
2914	Verio	47	176
3356	Level 3	46	536
3561	Cable & Wireless	59	592
7018	AT&T	35	136

The Rocketfuel data do not contain link bandwidths, and so in the absence of this information, we shall use the simplest possible assumption of equal bandwidth links (as in [27]). One exception to this policy is that we will investigate the impact of varying the peering link capacities because these links are often considerably different from backbone links in a number of respects, as a result of being created through negotiations between multiple parties.

3.2 Traffic generation

The units of traffic we shall manipulate will be *flows*. A flow represents the traffic between some source and destination during some time interval. We shall ignore time dependence here for simplicity, though some methods of optimization have been shown to be applicable to solving temporal problems [9, 15], and these methods could be easily generalized to apply here. Sources and destinations of traffic in IP networks are groups of IP addresses, often with a common *prefix*. Note though, that the groupings we use here are arbitrarily decided by the network operators, i.e. they do not have to correspond to a particular prefix, customer, router, or other logical structure in the network. The only constraint

is that we will not divide flows when routing them, other than across intra-domain MECPs.

For simplicity, we shall use flows aggregated to the level of traffic between PoP pairs. Note that this is not a requirement for the method. In general an operator might wish to conceal the addresses allocated to particular PoPs, or simply the number of PoPs in the network. Hence, they could use arbitrarily de-aggregated prefixes, (for instance break the ISP's address space into /24's), or they could aggregate address space allocated to routers. The choice depends on the balance between complexity and the level of optimization required (finer granularity requires more computation, but perhaps allows a greater degree of optimization).

We need to synthesize traffic matrices for our simulations, and so we extend the simple from [40]. We generate the traffic demand matrix between nodes using a gravity model with randomly chosen local traffic vectors. That is, we generate independent (mean one) exponential random variables

$X^k_{i,m} =$ the traffic at PoP i in network m in direction k,

where $k \in \{\text{in}, \text{out}\}$. The demand matrix elements giving the traffic from i to j in networks m and n are $D^{m,n}(i,j) = X^{(\text{in})}_{i,m} X^{(\text{out})}_{j,n}$. Although this method is extremely simple, it was shown in [40] to match real traffic-matrix statistics well. Note that the mean of the exponential random variables is set to one because this is a scale parameter, and as such controls the total traffic. As we will see below, we report relative performance metrics, so that the total traffic volume is not a key parameter.

3.3 Performance metrics

We evaluate the performance by measuring maximum utilizations. However, the maximum utilization on its own may reveal only the size of the traffic, which is being generated via a randomization process. In order to create a basis for fair comparisons we will output the performance (the maximum utilization) relative to the *measured routing* in the Rocketfuel data. Performance results are reported as a percentage showing the maximum utilization of a technique relative to the maximum utilization of the same traffic matrix given the measured routing. Smaller values indicate better performance. In some places we report the distribution of these relative performance values, in others, the average over some set of results.

4 Weight Optimization using Genetic Algorithms

The problem of intra-domain traffic engineering can be expressed thus: find the network routing parameters that balances loads on the existing links in a "beneficial" way. There is a very simple approach to solving the intra-domain traffic engineering problem, namely by using the shortest-path routing with a set of optimized link weights. This has the advantage of being easily implemented using current IGPs.

We call this approach the *shortest-path link-weight optimization problem* and it has been extensively studied [4–12, 15]. Despite the apparent limitation of shortest-path routing, the method has been shown (for realistic networks) to perform almost as well as the most general approaches to routing available, and to have many other advantages (see Section 2.1 for more details).

Take a network described by a graph $\mathscr{G} = (\mathscr{N}, \mathscr{E})$, where $\mathscr{N}$ is the set of nodes and $\mathscr{E}$ is the edges of the graph. We denote the number of nodes in the graph by N and the number of edges by E. We seek to choose a function $w : \mathscr{E} \to \mathbb{R}^+$, giving the link weights of each link, such that when we solve the All-Paths Shortest Path (APSP) problem, the solution minimizes the maximum utilization of the links in the network. We use the notation w_e, c_e, and f_e to denote link e's weight, capacity, and load, and the link utilization is defined to be $u_e = f_e/c_e$. Given a set of link weights, the APSP routing is the routing that minimizes for all $i, j \in \mathscr{N}$ the distances $d_{ij} = \sum_{e \in p_{ij}} w_e$ between nodes i and j, where p_{ij} is the set of links along the path chosen between i and j.

The problem of finding an optimal weight setting is NP hard [6], and so we must find heuristic approaches to the solution of the problem. Several proposed heuristic are based on GAs [7, 8, 11]. We use a slightly different GA here in order to make it easier to generalize to the joint TE problem. The chromosome for each member of the population is a vector containing w_e for each edge. We restrict these elements to be represented by K bits, restricting the range of values to $w_e \in [0, 1, \ldots, 2^K - 1]$. The GA algorithm is then:

1. **initialization:** create (randomly) an initial set of N solutions called the population, $\mathscr{P} = \{\mathbf{x}_i\}$
2. **while** not finished
   a. **evaluate fitness:** $f(\mathbf{x}_i)$ of each $\mathbf{x}_i \in \mathscr{P}$
   b. **generate a new population:** the offspring
      i. **selection:** select two parents from the population based on fitness.
      ii. **crossover:** combine the parents genes to form offspring.
      iii. **mutation:** with a probability q mutate each gene.
   c. **replace old population with offspring.**

However, in designing a GA there is a great deal of flexibility in each of the mechanisms listed here. We take the approach here of using simple techniques with the aim of demonstrating the concept rather than providing the best possible optimization algorithm:

1. **Crossover:** We use a single (random) point crossover.

2. **Mutation:** We perform mutation gene by gene independently, with some small probability q.
3. **Selection:** Selection is determined from the fitness function $f(\cdot)$ based on the maximum utilization of a given routing $f(\mathbf{x}_i) = 1/\max_{e\in E} u_e$, and *Roulette Wheel Selection*, i.e., given a set of solutions $\{\mathbf{x}_i\}$, we select a member of the population with probability $p_i = f(\mathbf{x}_i)/\sum_{i\in P} f(\mathbf{x}_i)$.
4. **Termination criteria:** We terminate the algorithm after a fixed number G of generations.

In addition, there are many tweaks one can apply to GAs to improve performance. The only one we use here is *elitism*, i.e. the retention of the best member of the population during each generation with no crossover or mutation. This results in a non-increasing maximum fitness for each generation (a property not guaranteed otherwise).

We use the *measured routing* as an initial value, seeded into the population. This initial value does not have quite the same importance as in many other optimization techniques, because it replaces only one of the initial population. Note we confine our weight values to a smaller range of integers than the Rocketfuel data, so our initial solution may have different routing from the measured routing, and hence our results will not all start at 100% performance.

4.1 Validation of the GA approach

We tested the above approach on a range of simulated networks in order to choose reasonable parameter settings (results omitted because of space restrictions). Our main parameters are the probability of mutation $q = 0.01$, the population size $P = 50$, the number of bits to use in representation of a weight $K = 4$, and 2 elite solutions were retained. We compared our results to those of Fortz and Thorup (FaT) using their code, performing $G = 10000$ iterations for both algorithms. Figure 1 (a) shows the performance of our approach and FaT as defined in Section 3.3 by the maximum utilization of the approach relative to the maximum utilization for the measured routing on the Rocketfuel networks. Both approaches produce similar improvements (though FaT performs 2% better overall). Figure 1 (b) shows the computation times. The GA times are better by 27% on average. Although these computation times are not insignificant in some cases, weight optimization techniques have a number of advantages. For instance, Roughan *et al.* [15] showed that one could get a large part of the improvement of weight optimization using a much smaller number of iterations, thereby creating a potentially favorable tradeoff between time and performance — we demonstrate the same phenomena in Section 5.3.1. Furthermore, [15] also showed that weight optimization could be performed to create a set of weights that were robust over a period of at least 24 hours (taking into account prediction errors, and daily variations). Hence, significant computation times can be amortized over such periods.

In some cases we observe that the performance of both algorithms was somewhat limited. For instance, in Figure 1, the performance improvement for ASN 7018 was only around 70%. In this particular case we investigated the reason, which was that there were two components of the graph that were poorly connected. In particular, three PoPs in Florida were connected to the rest of the North American nodes via a single pair of links. Given only two links, the opportunities for load balancing are somewhat limited. In the real network this would be reflected in the fact that the two links in questions would either have increased capacity, or the poorly connected network segment would have little traffic. This appears to be a relatively common occurrence in the Rocketfuel topologies, and hence we wished to assess how much our results were biased by such features. To do so, we excise the 3 Florida nodes (and 8 edges) from Rocketfuel ASN 7018, and perform the optimization on this new network. The results are shown in Figure 1 under the heading ASN 7018a. Clearly a great improvement was obtained for the reduced network. In the remaining work in this paper we will continue to work with ASN 7018a, the Rocketfuel topology without the Florida nodes, but we leave the other topologies untouched, thus providing some contrast as to the impact of this issue.

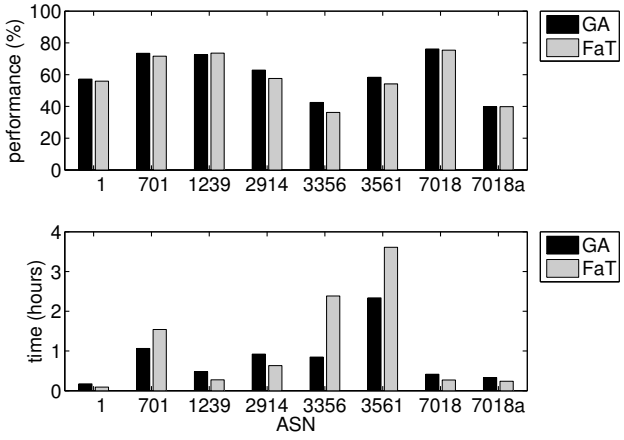

Fig. 1 Simple weight optimization using the GA for $G = 10000$, and Fortz and Thorup (FaT) also using 10000 iterations. The results show the mean relative performance for 30 random simulations, and compute times.

4.2 Computational complexity

The algorithm proceeds in a number of iterations G, with population size P, hence its computational cost is proportional to PG, but the critical factor in the computational cost

is the cost of evaluating the fitness function, which requires the solution to the APSP problem. We use a simple implementation of the Floyd-Warshall algorithm to perform this step (the algorithm has $O(N^3)$ computational complexity) and Figure 8 confirms cubic complexity. The all-paths shortest path problem can be solved more efficiently using better implementations of Dijkstra's algorithm but other elements GATEway will require $O(N^3)$ computations and so we do not try to improve the APSP algorithm here.

5 Symbiotic Optimization

The previous section considered optimization over only a single network, and similar results have been described elsewhere. We now describe the generalization of this approach to a pair of networks joined together at a set of *peering* links. The GA algorithm is extended to allow joint evolution of two "symbiotic" populations of solutions, one for each ISP. As in biological symbiosis the participants don't have to share all their genetic material. However, there is some information leakage in our initial approach, and we consider how to limit it in Section 6.

5.1 The problem

The problem we wish to solve here is the problem of optimizing the routing of two connected networks. In principle this is no more complex than optimizing one large network (comprised of the two inter-connected networks). However, business constraints restrict the type of routing allowed. For instance, transit routing is not allowed between peers. One peer cannot use another network's backbone to transit its traffic across the country using its own network only at the end points. Hence the simple generalization of shortest-path routing to the joint network created from inter-connecting the two peers will create unacceptable solutions.

Furthermore, as noted earlier, we wish to limit the exchange of information between the two peers. The joint shortest-path solution would require each network to share its topology, and traffic in detail. More precisely, take two networks $\mathscr{G}_1 = (\mathscr{N}_1, \mathscr{E}_1)$, and $\mathscr{G}_2 = (\mathscr{N}_2, \mathscr{E}_2)$, which are inter-connected by a set of peering links $\mathscr{Q}$, where for $q \in \mathscr{Q}$ we have $q = (n_1, n_2)$ where $n_1 \in \mathscr{N}_1$ and $n_2 \in \mathscr{N}_2$. We can create a joint network $\mathscr{G} = (\mathscr{N}, \mathscr{E})$, where $\mathscr{N} = \mathscr{N}_1 \cup \mathscr{N}_2$, and $\mathscr{E} = \mathscr{E}_1 \cup \mathscr{E}_2 \cup \mathscr{Q}$. We shall use the solution to the shortest-path (SP) link-weight optimization problem on a joint network as a basis of comparison, because we have substantial evidence [6, 9, 15] that it will be close to the best possible routing solution. To be clear, in this solution (which we call *joint SP*), the peering links have no special role, and we do not attempt to prevent transit traffic. Hence the solution is an unrealizable idealization, but we use it as a loose lower bound on performance, for comparison.

At the other end of the spectrum, we will also compare results with selfish routing, where each provider optimizes its own routing with information it can measure itself. This *selfish* solution will be poor because each provider cannot anticipate the changes the other will make to its inbound traffic. On the other hand, GATEway

1. can be computed with limited sharing of information;
2. prevents transit; and
3. is reasonably simple to implement with standard routing protocols (e.g. shortest-path IGPs and BGP).

We do this using the mechanism of *exit point pinning*. Given a traffic flow from network 1 to 2, we would choose a particular exit point, and pin this flow so that it uses that exit point. There are a number of mechanism one could use to implement such a pinning (see Section 5.5), and the pinning could be performed at a variety of granularities. As we have previously discussed, we shall consider PoP level flows. We also simplify by pinning based solely on source or destination, not both. In the examples we show source based routing, as it is slightly simpler to explain, though destination based routing (which is an equivalent, though transposed problem) would be easier to implement. For example, traffic from node i in network 1, to node j in network 2, would be pinned to peering link $q(i) \in \mathscr{Q}$ (note we can specify a peering link by its end points $q = (k,m)$, $k,m \in \mathscr{N}$ or its index in the set, e.g. $q = j \in [1,\ldots,Q]$). The exit point chosen for a given traffic flow is not necessarily the closest to the point of origin, so this is not hot-potato routing, but we do not need the full flexibility of a scheme like TIE [17].

Before we can continue, we must also briefly discuss the difference between Origin-Destination (OD) demand matrices, and Ingress-Egress (IE) traffic matrices. As noted earlier we will simulate using an OD demand matrix generated via a gravity model, which specifies the traffic from origin to destination in the joint network $\mathscr{G}$, and so is a $N \times N$ matrix, where $N = N_1 + N_2$ and $N_i = |\mathscr{N}_i|$ is the number of nodes in network i. Denote the OD matrix by D where its elements $D(i,j)$ are the traffic from origin i to destination j, and we can write D in the form

$$D = \begin{pmatrix} D^{1,1} & D^{1,2} \\ D^{2,1} & D^{2,2} \end{pmatrix},$$

where $D^{m,n}$ is the matrix whose elements $D^{m,n}(i,j)$ give the traffic from node i to j in networks m and n.

The IE traffic matrix describes the traffic matrix as seen internally on a single one of the networks, which is not the same as the demands (see [41] for detailed explanations of this phenomena). For instance, for network 1, the observed traffic matrix will not be $D^{1,1}$. Using pinning, we can easily construct an IE traffic matrix $T^{(k)}$ for network k from the

OD matrix. We simply take, for example

$$T^{(1)}(i,j) = D^{1,1}(i,j) + \sum_{m=1}^{N_2} D^{1,2}(i,m) I(q(i) = (j,*)) + \sum_{m=1}^{N_2} D^{2,1}(m,j) I(q(m) = (*,i)),$$

for all nodes $i, j \in \mathcal{N}_1$, where $*$ is a wildcard, and $I(\cdot)$ denotes an indicator function, i.e. $I(A) = 1$ if A is true, and 0 otherwise. The computation for $T^{(2)}$ is similar. Notice that the matrices $T^{(i)}$ may not follow a gravity model even where D does. Computing $T^{(1)}$ takes $O(N_1^3 + N_1^2 N_2)$ operations, and so the resulting computation is of similar order to the shortest-paths computation. The demands $D^{1,2}$ and $D^{2,1}$ are measurable by either party using flow collection. The internal demands $D^{i,i}$ do not have to be shared.

In addition, we need to be able to compute the traffic on each peering link q, which we can do by

$$r_j^{(1,2)} = \sum_{k=1}^{N_1} \sum_{m=1}^{N_2} D^{1,2}(k,m) I(q(k) = j),$$

$$r_j^{(2,1)} = \sum_{k=1}^{N_2} \sum_{m=1}^{N_1} D^{2,1}(k,m) I(q(k) = j),$$

where $\mathbf{r}^{(1,2)}$ and $\mathbf{r}^{(2,1)}$ are vectors of the loads on peering links. Both providers know the capacity of peering links.

Network operator i can now compute the shortest paths via the APSP, and hence compute the internal links loads on network $\mathcal{G}_i$ using only local information: the IE traffic matrices, a set of exit points, and link weights on $\mathcal{E}_i$.

5.2 GA solution

Consider the problem above. We wish to find a solution that limits the sharing of information to the necessary minimum, and yet allows optimization to take place. We shall apply the metaphor of *symbiosis* here, allowing each network to co-evolve without sharing all their genetic material.

We start by specifying the chromosomes — there will be four. For each network we use one chromosome to describe its weights, and another to describe the pinning positions. We separate the two groups of information as we may wish to perform cross-over and mutation in different ways for each type of gene. More specifically, each member of the population will be described by the vectors $\mathbf{w}_i$, and $\mathbf{q}_i$, giving the links weights, and pinned exit points, respectively, for networks $i = 1, 2$. As before, the weights are restricted to $[1, \ldots, 2^K - 1]$ and $q_i \in [1, \ldots, Q]$, where there are Q peering links. Network operator i holds $\mathbf{w}_i$ and $\mathbf{q}_i$. The values of the pinnings are shared, but the network weights are not, thereby keeping secret each networks' internal topology.

Each network uses the traffic matrices, pinnings, and its own internal weights to compute its own internal link utilization, and the peering link utilization. The information necessary to compute the joint fitness function (the maximum utilizations) is shared, so that each network knows the joint fitness of all members of the population. From this each performs selection, sharing the seeds used in pseudo-random number generation such that they each select the same population members. The two then perform cross-over, and mutation independently (only on the chromosomes they hold).

5.3 Evaluation

5.3.1 Performance

We test the performance of techniques by simulating using the methodology described in Section 3. That is, we choose a pair of networks whose topologies and interconnects are given by the Rocketfuel data, assume link capacities are equal, and we generate a random (joint) traffic matrix describing traffic inside each network, and between the two. We perform 10 realizations of each of the 21 possible pairs of network leading to a total of 210 simulations. For each simulation we compute performance, defined in Section 3.3 to be the maximum utilization of a technique relative to the maximum utilization of the measured Rocketfuel routing (smaller percentages are preferred).

The Cumulative Distribution Function (CDF) of the performance of each technique is shown in Figure 2. The y-axis show the proportion of tests with performance below the specified performance, so curves further to the left indicate better performance and there is no averaging over simulations in this figure. Note that we shall defer discussion of the "symbiotic 2" algorithm until Section 6, where we present an alternative algorithm that improves privacy (at a cost in terms of performance).

Unsurprisingly, the joint SP (Shortest-Paths) algorithm has the best performance. It is noteworthy that its performance ranges between 20 and 100% with an average of 46.6% (Table 1 summarizes the average performance). Summarizing, joint SP routing always improves performance in comparison to the measured routing on these networks, and the improvement ranges from being fairly small, to a factor of five, with the average being around a factor of 2. However, as earlier noted, the joint SP solution is unrealizable.

Given that this routing is unrealizable, and that the networks in question were not specifically designed to carry the simulated traffic, it is natural to ask how important the above improvement is. We can see this by considering how well we do using selfish routing, which should in principle account for the simulated traffic. The performance of selfish routing ranges to values greater than 120% (values over 100% indicate that we are actually worse off with this routing scheme). In about one third of cases, providers are worse off if they act selfishly. This result contrasts strongly with that of joint

SP routing, and so we use the joint solution as a benchmark against which to compare our approach.

The performance of the symbiotic approach is close to that of the joint SP algorithm. Its average performance relative to measured routing is 51.5%, so our method provides roughly a factor of two performance improvement, but it is realizable even with the privacy constraint.

Figure 3 shows the performance after each iteration for a single simulation of a specific network pair. Most importantly we learn from this graph that the majority of improvements in performance occur early on in the optimization. Hence, one could find useful tradeoffs between performance and speed. Graphs for other provider pairs, and other simulated traffic matrices also support this view.

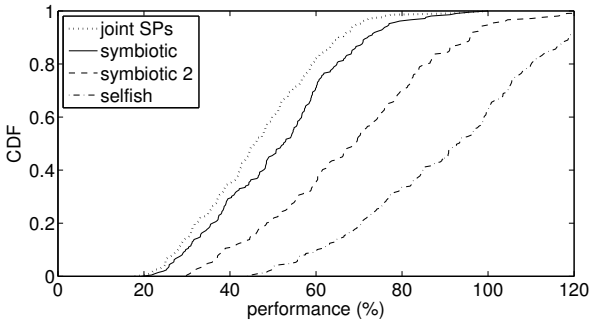

Fig. 2 The CDFs showing the performance of the TE techniques with respect to the measured routing with $G = 5000$.

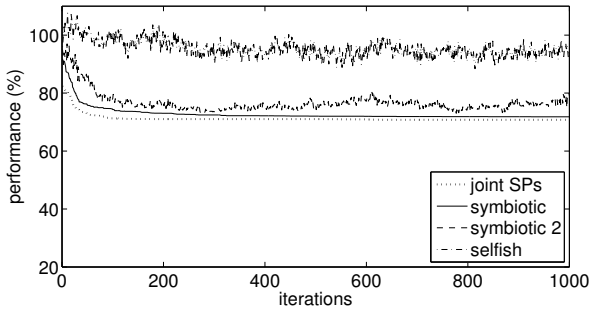

Fig. 3 TE across the Rocketfuel AS 1239 and 7018.

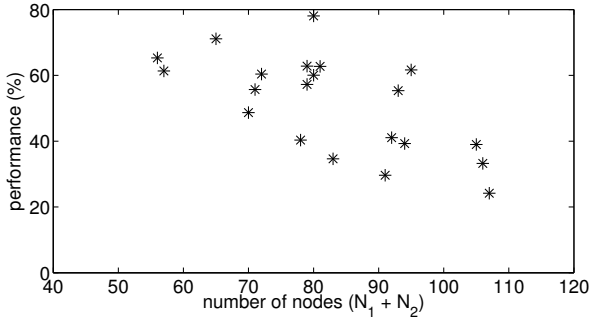

Fig. 4 Performance of the symbiotic algorithm as a function of the joint network size.

Additionally, we considered how various characteristics of the networks influenced performance. Figure 4, shows that the performance was correlated with the network size. We speculate that this is because larger networks provide more opportunities for route diversity, which may be beneficial for shortest-path routing optimization (we see a similar phenomena in Section 5.4 for larger networks).

5.3.2 Peering vs internal links

In the work above, we have deliberately kept things simple in having all link capacities equal. However, anecdotally, peering links are often supposed to be smaller than internal links. Peering links are built through negotiation between competitors. Neither party wishes to pay for the links, and so they are sometimes allowed to reach a state of congestion before any action is taken to upgrade the links. In comparison, anecdotal evidence suggests that most major backbones are relatively lightly utilized, and are likely to remain so under due to the requirements for failover capacity.

Figure 5 shows the relative performance of the algorithm as peering link capacity varies with respect to backbone capacity. The figure shows the maximum link utilization relative to the measured routing for the Rocketfuel networks 1239, and 7018 averaged over 10 simulations. The figure also shows the maximum peering link, and internal link utilizations. For normalized peering link capacities below about 0.4 the performance of the algorithm is dominated by the peering link performance, i.e. the maximum link load occurs on a peering link. Under such circumstances, the relative performance is dominated by a bin-packing problem, which unsurprisingly can be solved significantly better than the measured routing. On the other hand, as the peering capacity increases, the network performance becomes dominated by the internal link capacities.

Note that as the normalized peering capacity becomes large, the performance approaches the individual performance of network 1239 (shown in Figure 1) indicating that this network is the bottleneck in this scenario. However, despite the dominance of this component of the network, other link traffics are being reasonably balanced (as shown by the comparisons between the purely peering, and internal performance shown in the figure). This might be even better accomplished if we used a less simple performance metric such as considered below

5.3.3 Alternative metrics

The algorithm above has been shown to find a good min-max link utilization solution to the routing problem. However, network operators may not share this goal; they may wish to optimize other objective functions. A key advantage of GAs is their flexibility with respect to objective functions. We have tested our approach against the metrics drawn

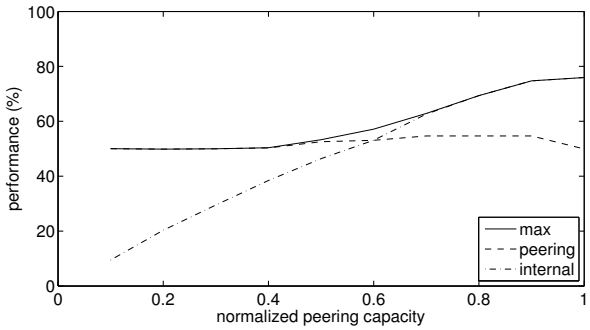

Fig. 5 Maximum utilizations of the network, internal links, and peering links as the normalized peering capacity varies.

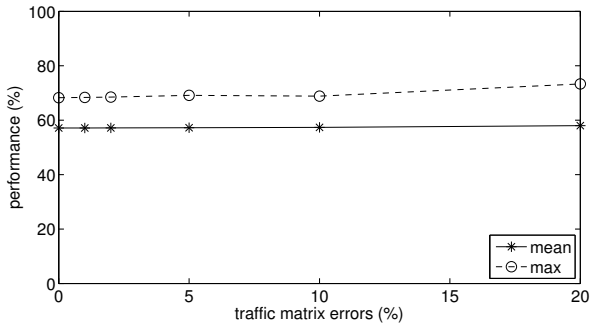

Fig. 7 Robustness results for Rocketfuel networks 1239 and 7018, averaged over 100 simulations.

from [6, 9]. It has the advantage that it incorporates congestion information from the whole network, not just the maximally utilized link. The metric of [6, 9] is given by a sum $\sum_e C(u_e)$, where $C(0) = 0$ and C is a piecewise-linear, increasing function of utilization (with increasing derivative). We then use fitness $f(\mathbf{u}) = 1/\sum_e C(u_e)$.

Figure 6 clearly shows that the new metric is optimized (in fact given the log y-axis the improvement is much faster than for the max-utilization). The figure shows not just the total congestion function, but also the function for each individual network, for a particular pair of Rocketfuel networks. The reason for showing the individual networks results is to show that gains are made for both networks, and that the gains do not depend on the ordering of the two (i.e. the maximum and minimum congestion functions are both being optimized simultaneously). Link utilization results are omitted but support the same view.

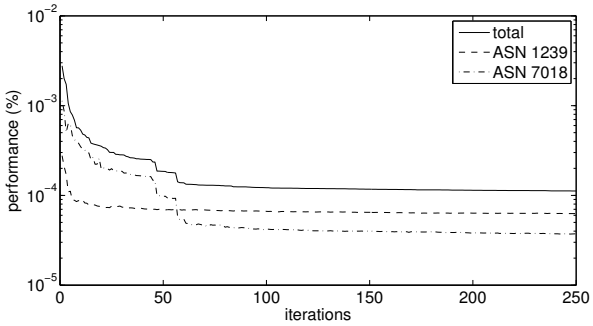

Fig. 6 Performance when minimizing $\sum_e C(u_e)$.

5.3.4 Robustness

TE is typically applied predictively, i.e. one measures the network, determines the routing to be used, and then this is applied in some future time interval where the traffic may not be identical to that measured. In addition, measurements themselves may contain errors, for instance where sampling or inference is used in data collection. Hence, robustness to measurement or prediction noise is a highly desirable characteristic of any TE algorithm. One of the advantages of optimal weight assignment is robustness to noise [5, 13, 15].

We test the robustness of GATEway by determining the optimal (or near optimal) routing using the symbiotic GA, but then measuring its performance on a network where a different traffic matrix is applied. For each initial OD demand matrix $D(i, j)$, we measure performance on a traffic matrix with multiplicative noise, i.e. $D_{\text{err}}(i, j) = D(i, j)\,[1 + \sigma N(i, j)]$, where $N(i, j)$ is an independent standard normal random variable, for each i and j, where we vary σ such that the standard deviation of the noise relative to the initial traffic varies from 0 to 20%. For each of the 10 initial traffic matrices we repeat this experiment 10 times, adding different noise each time, for a total of 100 experiments. Figure 7 shows the results for the Rocketfuel networks 1239 and 7018. The figure shows both the average performance, and the worst case performance (max). Even the worst performance over the set of 100 experiments shows great insensitivity to the errors. Similar results are observed for other values of peering capacity. It may seem surprising that the results are quite so insensitive to the input traffic, but this is roughly consistent with the results of [5, 13, 15], which showed remarkable insensitivity to noise in the simple weight assignment problem.

5.3.5 Computational Complexity

The issues surrounding computational complexity of this algorithm are essentially the same as those for the simple intra-domain problem, resulting in $O(N^3)$ complexity. Note though that the size of the network on which we evaluate shortest paths is the individual networks, not the joint network, and so the computational time is $O(N_1^3 + N_2^3)$ which is much faster than the $O((N_1 + N_2)^3)$ computational time for the joint network. Given two equal sized networks the reduction in computation time is a factor of 4. Figure 8 confirms the algorithms' complexities, showing computation times and fitted cubic curves.

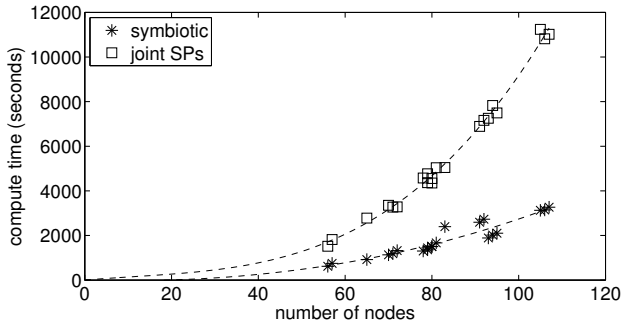

Fig. 8 The computation times of the algorithm with respect to number of nodes for the Rocketfuel topologies ($G = 5000$), and fitted cubic polynomials.

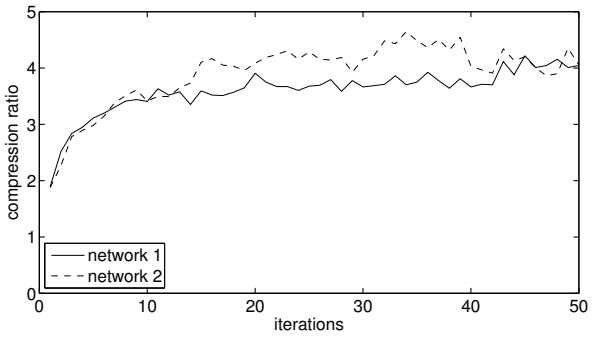

Fig. 9 The achieved compression ratios as a function of the number of generations of the GA ($P = 50$, $Q = 10$, $N = 50$).

5.3.6 Communications Cost

The implementation of this algorithm as a distributed algorithm requires a transfer of information between the two peers. The information to be transferred consists of:

1. The pinning points for each member of the population, for each generation.
2. The information needed to compute the fitness function (in our case, the maximum link utilizations).

The information require to compute fitnesses is small compared to the pinning information. The pinning information requires vectors of size N_i to be transmitted for each network i, for each member of the population, and at each generation. Hence the communication volume is $O(N_{\max}PG)$. Note also that each value to be transmitted is an integer in the range $[1,\ldots,Q]$, where Q is typically small (< 16), and can therefore be represented with around 4 bits without compression. However, after an initial random selection, the pinning vectors are not random, but are the result of a highly non-random process of evolution, and so are quit compressible. We tested this by writing the population of pinning vectors for each network to a file (for the example considered above with the two networks ASN 7018 and 1239), and using `gzip` to compress the files. Figure 9 shows the results with respect to the number of iterations (generations) of the GA. Compression ratios of around 4:1 were achieved within 10-15 generations. Thus the pinning data can be communicated with around 2 bits per value. Given parameter values used here (for instance $P = 50$, $Q \sim 10$, $N \sim 50$), the communications cost is < 1 kB per generation.

5.3.7 Other violations of assumptions

The largest assumption in all of this work is the "honest but curious" assumption. It is a fair assumption — the current Internet relies on this as well, given the relatively insecure nature of inter-domain routing at present. However, it is interesting to consider what happens if this assumption is violated. Imagine that one of the ISPs either lies about, or is mistaken in the data it provides to the algorithm, or chooses not to follow the routing determined by the algorithm. It is a simple matter then for the other ISP to measure the traffic across its peering links using flow capture, and from this determine that a problem has occurred. If the problem reduces their performance, then they may either renegotiate a new routing (via our algorithm or otherwise), or go back to their old routing, so they are no worse off than before commencing the use of this algorithm. The other ISP may possibly be better off in the short run through its dishonest behavior, but in the long run they are unlikely to make any more gains than they would by violating current BGP policies.

5.4 Multiple-party optimizations

The extension of this work to more than one party is quite straight-forward. N peers (in the sense of neighboring networks that do not allow transit) can perform the same type of optimization, such that each network retains the information about its own link weights, and shares appropriate pinnings with each peer. Given the GAs ability to cope with arbitrary fitness functions, the generalization is obvious. Figure 10 shows relative performance of the optimization as the number of participants increases. Again this seems to be a result of the increased diversity of routes in a larger network.

5.5 Implementation

The GA would use a protocol independent of the routing protocol. The optimization only requires concrete instantiation in routing once an optimal solution has been determined. There are two approaches to instantiate the derived routing using standard, existing routing mechanisms. Firstly, tunnelling techniques such as MPLS, or IP over IP encapsulation allow explicit choice of exit points. Such techniques have already been proposed for use in [17]. Tunnelling gives a high degree of control both over the exit points, and the

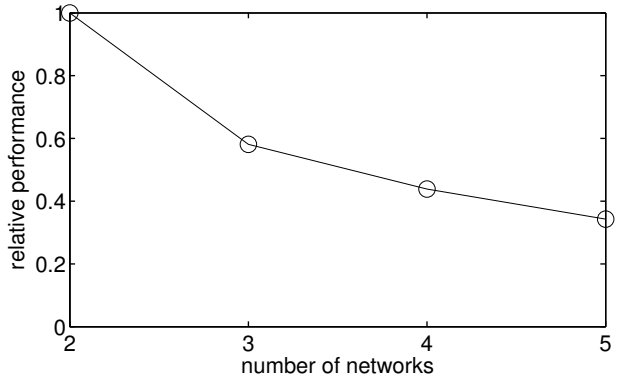

Fig. 10 Performance of multi-party GA as a function of the number of participants, relative to performance for two participants.

path taken by traffic, though in GATEway the route of tunnels would be chosen using shortest-paths (only exit points are fixed).

Alternatively, one could use BGP mechanisms to alter exit points. Mechanisms such as local preference, and MEDs are used to control exit points. These apply control across a whole network (e.g. the exit point for all source nodes for a particular destination would be the same), which implies a destination based pinning. We showed that such a pinning would still provide excellent gains in performance. Even if BGP is used, only exit points are changed, so announcements outside the AS are not needed, and iBGP convergence times will be much shorter than eBGP convergence times.

At present TE is typically performed as needed, in a rather *ad hoc* fashion. However, with automated optimization it could be performed regularly. The time interval at which we perform TE is a tradeoff between more precise optimization (using a fine-time grain), and the cost (potential packet loss during routing reconvergence) of frequently changing network routing. As noted, we do not need to wait for slow eBGP reconvergence, and so the impact of routing changes would be quite small. On the other hand, shortest-path routing optimization has been shown to work well over for traffic with daily variations [9, 15]. So it seems reasonable (as a starting point) that the TE should be performed once per day.

There could be a short period between the optimization and implementation phases where the routing on the two networks not synchronized (in the sense that the two are not both using the same optimized polices). This cannot cause route loops as the routing protocols *are* synchronized, but may result in a brief period of suboptimal routing. The length of this period would be determined by how quickly the agreed routing can be implemented in the respective networks. With automation this could be accomplished in seconds to minutes, but once again note that the only effect would be some suboptimality in routing, and we have already shown that the shortest-path routing approach is quite insensitive to noise, and so we should no expect serious consequences during this phase.

Furthermore, network providers often have a maintenance window (in the early morning when traffic is light) for making network changes so that they have minimal impact on customers. It would be desirable to schedule TE activities at the end of this interval. As the maintenance window is chosen to be during a period when traffic is light, some small degree of suboptimality in routing will have negligible impact. Furthermore, most network changes happen during the maintenance interval, and so performing TE at the end of this interval allows the network to adapt in a timely fashion to any topology changes.

6 Privacy Maximization

The above approach to joint network optimization limits information sharing, but there is still some leakage through the pinning vectors and fitness functions. The joint fitness calculation requires the ISPs to share maximum utilization data. This problem is alleviated in part through the use of the utilization metric of [6, 9], but can be improved further.

One of the advantages of the GAs is that the fitness function can be arbitrarily chosen. All we really need to know are the selection probabilities for each member of the population of possible solutions. We have a polynomial-time algorithm for constructing these probabilities, and therefore Yao's two party protocol applies. This is now a well researched area (for instance see some of the reference at [35]), and so, given space limitations, we only briefly describe the approach. There are three steps: firstly, we must solve the APSP for each network, given its internal weights. This can be done internally by each provider. Then these routes must be used to compute the load on each link from the OD demands. For internal links $f_e = \sum_{i,j=1}^{N} D(i,j)I(e \in p_{ij})$. This can be directly computed where $i, j \in \mathcal{N}_k$, but for $i \in \mathcal{N}_k$ and $j \in \mathcal{N}_m$, $k \neq m$ we need to break the indicator into two parts

$$I(e \in p_{ij}) = \sum_k I(e \in p_{ik})I(q(i) = (k,*)) + \sum_m I(e \in p_{mj})I(q(i) = (*,m)),$$

where $q(i)$ is the peering link for traffic originating at node i. The number of bits for $D(i,j)$ is $O(nN^2)$ where we represent the values with n bits, while for the indicator functions there are $O(EN^2 + N\log Q)$ bits. Yao's protocol's communications cost is linear in the number of bits [34], and so requires $O(nN^2 + EN^2 + N\log Q)$ overhead. The above computation has to be performed for each edge, so given that typically $E > n$, and we can write the complexity as $O(E^2N^2)$. The third step is to compute the maximum of these values, for which a standard version of Yao's protocol is sufficient, and with comparably negligible overhead (as

is the overhead of computing the peering link loads). Additionally, secure operations can be composed, hiding intermediate data. Hence it is possible to perform a step of the symbiotic algorithm which satisfies the definition of privacy preserving, in the sense that the two ISPs need not share (i) utilization data, (ii) pinning data, (iii) any other details of their internal network. We call this solution *privacy-max* and note its performance is the same as the previous symbiotic solution. The cost for using this approach is an increased communications cost associated with performing Yao's protocol.

An alternative to strict privacy preservation via Yao's protocol is to separate selection into the two networks. More precisely, each network computes its own fitness function, and each uses this to select one parent for cross-over. The two networks share the pinning information which is needed to compute link utilizations (again Yao's protocol could be used here to avoid this information being shared). However, the two network use completely independent fitness functions — the fitness functions need not even be the same, thus avoiding any need to share this information. There is a cost in performance. The method (which we refer to as "symbiotic 2"), does not perform as well as the simpler algorithm. The results for this independent symbiosis are shown in Figures 2 and 3, and Table 1 summarizes the performance of all methods considered here. The average performance after 5000 generations is 68.4% as compare to 51.5% for the previous algorithm, though still a considerable improvement on the selfish solution. The performance reduction occurs because, although we still use elitism, each network chooses its own elite member of the population without knowledge of the fitness function of the other network. As a result, the chosen elite members of the population are not necessarily elite from the point of view of the other network or a joint fitness function. Hence performance (as measured by the joint maximum utilization) is no longer monotonic. Figure 3 shows this non-monotonicity. The final solution is actually worse than some of the solutions chosen along the way, but without knowledge of the joint fitness, we have no way to know this, and choose the better solution.

Note that the results for "symbiotic 2" also illustrate another important point. In these examples we use *different* fitness functions in the two networks. The fitness are computed independently, so this is easily incorporated.

7 Conclusions and Future work

This paper presents GATEway, a set of algorithms for joint TE between two networks who do not wish to make disclosure of information about their networks. We demonstrate a distinct advantage to combining information, but we present methods here that allow combination of data, without needing to share it. Such approaches could have a significant impact on the way network operators interact.

There is a great deal of interesting work leading on from this paper. Initially we may find improvements of the GA, but the GA is highly flexible, so we anticipate being able to apply modifications to solve more sophisticated problems considered in the TE literature, for instance optimized routing that works well for failure scenarios [18, 19]; that can find single weight settings for a range of traffic matrices [9, 15]; where additional constraints are imposed; or applied to TIE routing [17].

The approach we have proposed here for a specific problem is actually quite general. It could be applied to other network problems, for instance inter-ISP capacity planning, and perhaps it is also possible to extend these methods outside of the networking world. The important point is that GAs make the approach inherently flexible to a range of problems where information sharing is undesirable.

Acknowledgement

We wish to gratefully acknowledge the use of M.Thorup and B.Fortz's code for the simple weight optimization, and for the use of the Rocketfuel data. In addition, M.Roughan was partially supported for this work by Australian Reseach Council grants DP0665427 and DP0557066.
