ABSTRACT

The FM9001 is a 32-bit, general-purpose microprocessor whose specification and netlist-level implementation have been formally described in the Nqthm logic. The FM9001 netlist has been mechanically checked to implement its specification with the Nqthm theorem-proving program. This report includes the entire formalized input: specification, implementation, and theorems, all of which have been checked with Nqthm. The FM9001 microprocessor has been fabricated as a CMOS gate array by LSI Logic, Inc. We have been testing the fabricated FM9001 for over two years and we have not yet discovered any flaws. Also included in this report is the netlist from which LSI Logic fabricated the FM9001. This report is intended to permit an Nqthm user to completely redo the FM9001 proof, and also to formalize and verify other hardware in the `DUAL-EVAL` hardware description language.

Keywords: hardware verification, formal specification, hardware description language, circuit synthesis, CLI short stack, formal methods, FM8501, FM8502, FM9001, Piton

Chapter 1

OVERVIEW

The FM9001 microprocessor is a general-purpose 32-bit device whose gate-level netlist design implementation was developed using a theorem-proving environment in conjunction with a traditional CAD system. This netlist was translated to LSI Logic's NDL (Netlist Description Language) for physical implementation. The behavioral specifications for the FM9001, the definition of the hardware description language (HDL) used to represent the design of the FM9001, the simulator for the HDL, and the verification of the FM9001 were all carried out using the Boyer-Moore theorem-proving system Nqthm.

This document presents the details of the FM9001 development, specification, and verification. First, we give a little history of the FM9001 project followed by a summary of our results. The remainder of this document is devoted to giving the details of the specification and verification of the FM9001 from an Nqthm user's point of view. Thus, we imagine that the reader probably has some familiarity with Nqthm.

The FM9001 behavioral and design specifications, the hardware description language and its semantics, the FM9001 correctness proof, and the preparation of the FM9001 for fabrication were performed entirely by Bishop C. Brock and Warren A. Hunt, Jr. The FM9001 microprocessor was manufactured by LSI Logic, Inc., who also performed post-manufacture testing [1]. More thorough testing was performed by Kenneth Albin by building a purpose-built single board FM9001 computer with an interface to a logic analyzer. Lawrence Smith interfaced the FM9001 to Tektronix chip tester, which allowed much more complete testing. Matt Kaufmann proved the ALU interpretation lemmas (Section 13.2), and assisted with proving reset properties (Sections 2.13, 11.3, 12.1). Ann Siebert did much of the work on the recognizer for well-formed circuit descriptions (Section 5.4). The arithmetic libraries were taken largely from existing libraries at Computational Logic, Inc. (see Chapter 3).

The first draft of this report was written by Warren A. Hunt, Jr. and Matt Kaufmann. The report was subsequently edited by Warren A. Hunt, Jr. and Robert

S. Boyer. Ann Siebert wrote Section 5.4, and William D. Young helped with Section 5.1.

All of this work was performed at Computational Logic, Inc., as a research project. This effort was supported in part by ARPA.

1.1 HISTORY OF THE PROJECT

The FM9001 effort started in earnest when we (Bishop Brock and Warren Hunt in November of 1989) defined a simulator, which we called `DUAL-EVAL`, for a language that was general enough for representing the design of a microprocessor along with its memory system [10, 15]. Representing circuits as data was a turning point in our efforts at hardware specification. Previously Hunt [13, 14] had represented hardware with functions in the Boyer-Moore logic. We also investigated representing circuits as predicates [8], in the tradition of the HOL hardware verification community [11]. Neither of these approaches permitted operating on a "circuit" directly; that is, instead of having a constant that could be interpreted we were trying to represent circuits as expressions in a logic. Why it took so long for us to realize that neither approach would be satisfactory (as evidenced by the CAD community's approach to circuit representation) is difficult even for us to understand.

The point of representing circuits as data as opposed to representing circuits with functions can be likened to representing circuits as a netlist in a purpose-built netlist language as opposed to representing circuits as C-language code. That is, we want to use the C-language code to implement simulators, recognizers, synthesizers, etc., for operating on our netlists, and not attempt to implement a netlist as a C-language program—the CAD community has operated with this paradigm for many years. Thus, when we say we have defined a hardware description language (HDL) we mean that we have defined a recognizer function (in the Boyer-Moore logic) that determines whether some netlist is well formed and a simulator function (also written in the Boyer-Moore logic) that, given input data, simulates well-formed netlists. Representing circuits as data also permits the verification of tools used to operate on the language; that is, it is possible to prove the correctness of circuit synthesis functions. However, mechanically proving the correctness of large circuit designs by reasoning about their simulations is more complicated and difficult than our previous approach that used direct representations in the logic.

Immediately prior to the definition of the `DUAL-EVAL` simulator and language recognizer we had defined several different hardware description languages which differed in representational power. For instance, one such language (with associated formal simulator) was called `WAVE-EVAL`, which could simulate a less restrictive class of circuits than `DUAL-EVAL`. However, it seemed too hard to reason about. Another language/simulator that we defined was named `HEVAL`[9], but this early language was restricted to combinational logic circuits only. Once we had defined `DUAL-EVAL`, we spent most of our time building up automated reasoning tools to

ease the analysis and verification of circuits described in the `DUAL-EVAL` language, at least until we had automated the process sufficiently to verify the FM9001 design. In actuality, the evolving FM9001 design was a "technology driver" for the development of the `DUAL-EVAL` language. Another part of the HDL development was the evolution of its language recognizer. At first, the recognizer checked for proper syntax and absence of combinational circuit loops; however, over time the recognizer was extended to check for loading and fanout violations, timing properties, well-formedness of LSI Logic names, and a host of other properties. Every time we formalized and verified a circuit, we mechanically translated it to LSI Logic's NDL (Network Description Language), and then with LSI Logic's toolset we compiled the resulting netlist. Each time we found a problem during the compilation or subsequent library linking, etc., we further restricted the class of circuits we admitted by changing the circuit recognizer to disallow the problem encountered. Later Ann Siebert produced a much nicer circuit recognizer that produced error messages; the original recognizer only returned true or false. Another facet of the design process was ensuring that circuits could be tested. Bishop Brock implemented a parallel stuck-at fault simulator that we often used before we even verified a circuit.

The FM9001 was passed off to LSI Logic, Inc., for manufacture at the end of July of 1991. We received FM9001 microprocessor chips some six weeks later. Warren Hunt built a simple test jig that allowed us to check the timing of the various output signals. In 1992, Ken Albin built a single-board computer using the FM9001 microprocessor; this board was constructed in such a way that all of the FM9001 microprocessor signals could attached to a logic analyzer. We ran several programs to check to see if the manufactured part worked as we expected it to [1]. In 1994, Larry Smith interfaced the FM9001 to a Tektronix LV500 chip tester and performed more thorough testing of the fabricated device than was possible with the single-board computer. To this point, we have not found a single operational bug.

Entirely separate from the FM9001 project was J Moore's use of the `DUAL-EVAL` simulator in the succesful specification and verification of a circuit for Byzantine agreement [20]. By using the `DUAL-EVAL` circuit recognizer predicates, he was able to translate his verified circuit into LSI Logic's NDL without needing to understand LSI Logic's tool suite.

1.2 THE FM9001 SPECIFICATION

The FM9001 is specified at four levels of abstraction—user, two-valued, four-valued, and netlist; these are shown in Figure 1.1.

- A high-level behavioral (user-level) model that operates as an instruction interpreter for FM9001 programs;

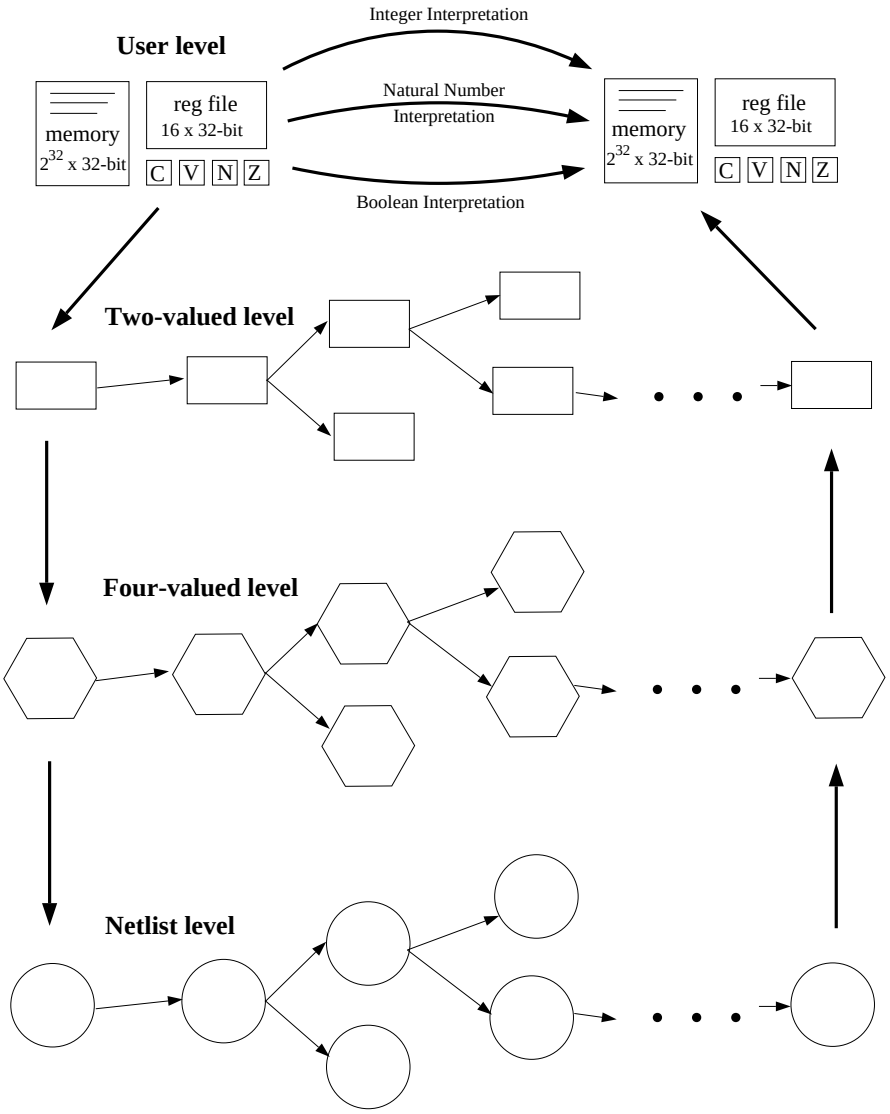

Figure 1.1: Specification Levels

- A Boolean (two-valued) model that "mirrors" the intermediate, register-transfer model;
- An intermediate, (four-valued) register-transfer model that links the low- and high-level specifications for verification purposes; and
- A complete gate-level (netlist) model presented in the `DUAL-EVAL` HDL.

The high-level and the register-transfer models are captured as executable Nqthm logic functions. The semantics for the gate-level implementation, which is described by an Nqthm constant, is given by our hardware description language simulator, `DUAL-EVAL`. Even though we often prove that parts of the register-transfer level are equivalent to the "Boolean level", we do not have a complete Boolean level; this is an artifact of our verification approach. The gate-level model includes all of the logic required to physically construct the FM9001, including the test logic. To have LSI Logic manufacture the FM9001, we translated only the `DUAL-EVAL` netlist into LSI Logic's Network Description Language (NDL) and provided the test vectors required by LSI Logic, Inc.

The implementation of the FM9001 is described as a `DUAL-EVAL` netlist containing a reference for every primitive gate, latch, register, I/O buffer, and wire that is required for the FM9001 implementation. Both the syntax and the semantics of this netlist have been mechanically checked: the netlist is well-formed and it has been proven to implement the FM9001 specification. We have a formal definition of acceptable netlists; that is, we have a predicate that identifies well-formed netlists.

The proof of correctness of the FM9001 gate-level design consists of three major lemmas. First, we have shown that the FM9001 can be forced to a known state, i.e., reset, by a suitable sequence of inputs. This proof is carried out using the gate-level models; the concept of resetting the machine does not appear at the behavorial level of the instruction interpreter. Second, we show that given a set of initial conditions, the gate-level model correctly implements the high-level specification. This proof involves both time and data abstractions to link the clock-cycle based semantics of the gate-level FM9001 model with the high-level instruction interpreter. Finally, we show that the state at the end of the reset sequence satisfies the initial conditions for the previous lemma. This sequence of results provides the formal basis for believing that behavior specified by the instruction interpreter is implemented by the gate-level design. Of course, any physical flaws could invalidate everything. We did, during the design of the FM9001, make provisions for thoroughly testing the manufactured devices.

Physically, the FM9001 is a general-purpose CMOS 32-bit microprocessor. The FM9001 features a two-address programming architecture, five addressing modes, multiple processor bus capability, and extensive arithmetic flag support. At 25 MHz the FM9001 only requires 70 mA of power exclusive of I/O drives; the clock rate may be reduced for lower power consumption. All the latches are connected by a scan chain for testing purposes, except for the register file, which has dedicated test logic.

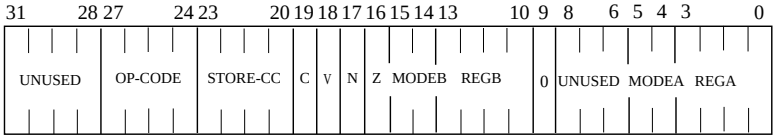
The FM9001 executes instructions by fetching operand A, operand B if necessary, computes a result, and stores the result in the location referenced by operand B, if necessary. Figure 1.2 shows the two FM9001 instruction formats, a two-address instruction or an immediate datum instruction. The two formats only differ in origin of operand A. In the immediate datum case the nine-bit datum in the instruction is sign-extended to 32-bits; otherwise, operand A is selected in the same manner as operand B. Except for the immediate datum mode, operand A and operand B are selected by any of the following modes: register direct, register indirect, register indirect with pre-increment, and register indirect with post-increment addressing mode. Thus, operand A has five addressing modes and operand B has four, where every addressing mode for both operand A and B works with every instruction. The 15 different arithmetic instructions are listed in the table, as are the different conditions that are to be checked for each instruction in order to see if the computed result is to be stored. Each instruction also contains four bits that determine individually whether the arithmetic flags (carry, overflow, zero, and negative) are updated.

The FM9001 programmer's state is shown as a part of the user level in Figure 1.1. This state includes a general-purpose 16-element register file, four arithmetic flags, and the external memory. Register 15 is usually used for the program counter address, but in all other respects operates like the other registers. To perform a conditional branch, operand A is added to the program counter, and the result is conditionally stored based on the `STORE-CC` field of the instruction. Since the results of any instruction may be conditionally stored, there are no differences between control and data operations. This is even true of the program counter because the implementation actually allows any of the 16 registers to be used as the program counter.

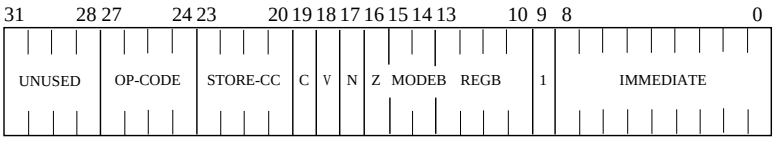
The FM9001 specification was derived from the FM8502 specification [14]. There are three main differences. The FM9001 has the ability to conditionally store every result—only conditional moves were permitted in the FM8502. The FM9001 performs the post-increment operations as each operand is fetched; the FM8502 post-increment operations were done after both operands were fetched and the result was stored. Lastly, the FM9001 has an immediate data mode for operand A; the FM8502 did not have this feature. The ALU operations remained the same as did the fetch-execute cycle. We did this to ensure that the Piton assembler [19] for the FM8502 could be easily transported to the FM9001.

The two-valued and the four-valued specification levels are artifacts of the approach we used to mechanically check the implementation of the FM9001. The two-valued level can be thought of as a Boolean model of the implementation with the tri-state memory interface bus abstracted away. The four-valued level has functionality similar to the two-valued level, except the tri-state memory bus is included; it is at this level that we prove that the FM9001 can be reset. The netlist-level specification describes the actual Boolean gates and latches, test logic, and I/O buffers used to implement the FM9001.

TWO-ADDRESS MODE



IMMEDIATE DATUM MODE



MODE	OPERAND	DESCRIPTION
00	Rn	Register Direct

Figure 1.2: FM9001 Instruction Word Formats

Before giving an informal statement of our chief result about the FM9001, we describe that statement in terms of Figure 1.1. The user-level operation of the FM9001 is shown at the top by arrows transforming a memory, register file, and flag state to a new user-level state, which results from executing one user-level instruction. This transformation is shown at the top of Figure 1.1. The correctness of the implementation is stated by mapping a user-level state down to a netlist-level state (see the lower left corner), executing the `DUAL-EVAL` simulator on that state with the FM9001 netlist-level implementation, and then mapping the resultant state back up to the exact same final user-level state. Further, the figure is drawn to indicate that more steps are required to implement an instruction at the lower levels than at the user level.

Here is an informal statement of the chief result proved about the FM9001. Let h be the hardware netlist that we have constructed for the FM9001. We have proved that for each FM9001 user-visible state, s, and for each positive integer, n, there exists a positive integer c such that the result of running the user-model of the FM9001 (the function `FM9001`) n steps can instead be obtained by simulating h and s under the `DUAL-EVAL` semantics for c steps. In precisely stating the theorem, we arrange to supply the `DUAL-EVAL` semantics with a transform (obtained with `MAP-DOWN`) of s, and afterwards we do a reverse transformation (with `MAP-UP`) to obtain the final user-visible state. Futhermore, in making the statement precise we stipulate that the external stimuli, i, to the chip do not enable a hold, a reset, or a test input for the c clock cycles. The fact that n and c are different reflects the fact that a single FM9001 instruction takes several clock cycles to emulate at the `DUAL-EVAL` netlist level. The precise statement of this correctness result is:

```
Theorem.  FM9001=CHIP-SYSTEM-SUMMARY

(let ((h (chip-system$netlist))
      (c (total-microcycles (map-down s) (map-up-inputs i) n)))
  (implies
   (and (fm9001-statep s)
        (no-holds-reset-or-test i c))
   (equal
    (fm9001 s n)
    (map-up
     (simulate-dual-eval-2 'chip-system i (map-down s) h c)))))
```

This theorem is the final event of the file "proofs.events". The function `MAP-DOWN` creates an FM9001 internal state appropriate to begin the execution of instructions. See the file "final-reset.events" for a set of lemmas that prove that such a state can be reached as a result of the reset process.

The following chart is a partial reproduction of a chart in Appendix III of *A Computational Logic Handbook*, by Boyer and Moore [7]. We added the last line. This information was constructed by a static analysis of the final FM9001 library

produced by the Boyer-Moore theorem prover.

	Number of lines in understandable statement	Concept depth of statement	Max concept depth in proof	Number of supporters	Lines of supporters	Depth of proof
85 FM8501	991	157	152	230	2171	18
86 Goedel	864	48	40414	1741	20002	58
91 FM9001	1112	120	128	1894	28784	46

Appendix III also contains the definitions of these concepts. The "understandable statement" of a theorem is the prettyprinted text of all the definitions used in the theorem except for Boyer-Moore primitives. The number of lines for the understandable statement of the FM9001 proof could be considered to be as high as 9992. The 1112 lines reported above is the sum of the first two lines of the chart just below.

	Prettyprinted Lines
User-level semantics of FM9001	915
Statement of theorem	197
Semantics of HDL	3459
FM9001 implementation description	3479
Existential witness for the clock	1942
Total:	9992

To get a rough measure of the size of the FM9001 proof, J Moore modified the theorem prover to count its smallest steps. By adopting a suitable collection of derived inference rules, a formal line-by-line proof using those derived rules can in principle be constructed for each proof step. Among our one-step rules are tautology recognition, instantiation, *modus ponens*, equality rewriting, and cross-multiplication and addition of inequalities.

The number of such proof steps for the FM9001 proof is at least six million. That is, more than six million lines of formal proof were "virtually constructed." It would be easy to increase this number by reducing the size of our proof steps. For example, the cost of substitution-of-equals-for-equals in HOL [12] is not constant (it is 1 in our count of proof steps) but is proportional to the depth at which the target occurrence is found. Similarly, we recognize very large `IF` expressions as tautologies but charge only one step. We have expressions containing more than 50 `IF` expressions through which there are more than 10^9 branches; however, since

the theorem prover prunes the branches dynamically, it did not have to explore all branches.

The total number of primitive proof steps investigated by the theorem prover during its search for the FM9001 proof was more than nineteen million. This means that approximately 32% of all the investigated steps were actually "kept." The term clausifier was called about eighty thousand times. The function that determines the type of a term was called almost fifteen million times and the rewriter was called more than eleven million times.

None of the figures given above for number of lines of statement or proof should be taken too seriously because they were computed prior to our proving a number of additional theorems presented in this report. Furthermore, the counting of lines of formal mathematics is a rather dubious endeavor; thus, for example, in counting the 915 lines of the user-level semantics, we did not count comment lines. Our presentation of such figures, however, does indicate that the theorem proved is a rather large one—it would take almost 200 pages of paper to print it! We believe that the use of computers to check such large theorems is essential because it would be difficult to manipulate such lengthy formulas by hand.

1.3 SUMMARY OF THE PROOF

Users of Nqthm know that there is more to completing a significant proof effort than simply stating the desired theorems and letting the prover prove them. Instead, one needs to prove a number of auxiliary lemmas, and even to define many auxiliary functions. The requirement for such creative effort leads to choices that form a style of proof. In this section we give an overview to the style of definition and proof that we have used in the FM9001 effort.

Our basic approach to the FM9001 specification and verification uses a formalization of an HDL (Section 5.1) based on the four-valued logic introduced above and defined in Chapter 4. The entire implementation netlist for the FM9001 is defined within our HDL. Our specifications are written as Nqthm functions. The goal of the proof effort was to demonstrate that the netlist implementation does indeed satisfy our behavioral specification, as diagrammed in Figure 1.1.

In order to carry out this proof, we made a number of stylistic decisions. For instance, we generally keep functions disabled, especially non-recursive functions, providing enable hints when their definitions are required. Hence we tend to prove rewrite rules about our functions that capture their most important properties. We made a large effort to automate much of the verification of modest-sized HDL modules. We did this by writing a number of Lisp functions and macros that generate appropriate events, with appropriate hints. We also proved lemmas for expanding appropriate calls of the semantic function for our HDL during proofs. We even defined a few Lisp reader macros in order to provide abbreviation mechanisms for constants.

The vast majority of this proof was carried out using a version of Nqthm that has

been publicly available since 1987. That system, however, did not contain certain important features, notably the `COND`, `CASE`, and `LET` constructs and the ability to deal with collections of events (including a `DEFTHEORY` event and `ENABLE-THEORY` and `DISABLE-THEORY` hints). Therefore, we actually used the `Pc-Nqthm` "Proof-Checker" interactive enhancement of Nqthm, [16], which includes these features as well as an "interactive" capability. Since we did not take advantage of the latter capability, we were able to replay the events in the more recent Nqthm-1992 system, which has incorporated the features that we needed, without using Pc-Nqthm.

Some parts of the total effort were done rather independently, and yet Nqthm requires a linearly-ordered event list. That is, Nqthm does not directly "understand" the notion of starting with a library, extending it in two different ways, and then merging the results in order to obtain a single library. Hence, suppose we have a library "lib1", which we extend to a library "lib2". Also suppose that separately, we also extend "lib1" to library "lib3". Then typically we merge "lib2" and "lib3" by adding a number of events to the beginning of "lib3" that restores the theorem prover "state" to what it was at the end of "lib1", and then putting the rest of "lib3" after that. That is, we end up with the event sequence obtained by appending together (in this order) "lib1", "lib2", extra enable and disable events, and finally "lib3". Details can be found in the body of this report.

For a description of the official syntax and semantics of the Nqthm-1992 logic, see Chapter 4 of *A Computational Logic Handbook*[7] or the revised version of that chapter which is distributed with the on-line documentation of Nqthm-1992. Nqthm-1992 may be obtained via anonymous FTP from Internet site `ftp.cli.com`.

1.4 ORGANIZATION OF THIS REPORT

In spite of the explanation above about our occasionally ad-hoc ordering of events, we have taken the simple approach of organizing this report around our final sequence of Nqthm events. In order to make the organization somewhat palatable, we have imposed a chapter structure that groups related event files.

Actually, the first chapter after the present one is a bit different: it contains descriptions of all of the Lisp files that we have used in this proof effort, one per section. These files define a number of Lisp utilities that we use to generate Nqthm events. As we explain in the next section, these utilities provide "abbreviations" for Nqthm events but are not strictly necessary. After that, each section corresponds to exactly one Nqthm event file, and the names show the correspondence. For example, Section 5.1 is called "DUAL-EVAL," and corresponds to the file "dual-eval.events". This file may be found in the chapter entitled "The Syntax and Semantics of Our Hardware Description Language," which contains not only the definition of our semantic function `DUAL-EVAL` (in the section mentioned just above) but also contains several related sections, each corresponding to a different Nqthm event file. The next chapter uses a similar naming convention.

Chapter 2

LISP-FILES SUMMARY

This chapter contains a number of Lisp utilities, including ones that transform various types of input into Boyer-Moore event forms.

2.1 SYSDEF

The file "sysdef.lisp" is what we use to build the system. When we load this file into Nqthm-1992, the main things that happen are that a number of Lisp utilities are loaded, as described in Chapter 2, and then the various event files are run, as described in the chapters following Chapter 2. Thus, we load this file when we have made changes and want to check that the sequence of events still runs successfully.

As described in Section 1.3 above, we use some of our Lisp utilities to automate the creation of Nqthm events. For example, much of the control logic in the FM9001 chip is generated (in the form of Nqthm events defining this hardware) from higher-level specifications, using Lisp macros that we have written for this purpose, as described in Section 10.3. Although this has been a useful technique for *obtaining* Nqthm proofs, it is a bit flawed from the point of view of providing *assurance* that appropriate properties of the FM9001 have really been verified. For example, we could have slipped into one of our utilities a redefinition of `PROVE-LEMMA` so that it would always succeed. Or we could have simply executed `(SETQ TRUE FALSE)`. So, in order to obtain an "official" run of our events in the latest (and probably final) release of Nqthm (i.e., Nqthm-1992), we have created a single event file, "fm9001-replay.events", that can be checked in Nqthm with the function `PROVE-FILE`, without any Lisp utilities loaded. This events file is created by loading the file "sysdef.lisp", which (as described above) loads a number of macros, runs the various event files, and then executing the form `(LIBRARY-TO-EVENTS "fm9001")`. The extremely careful reader of this report may wish, in fact, to construct that file in order to see exactly what forms were dynamically computed for submission to Nqthm.

2.2 SYSLOAD

The file "sysload.lisp" is included among the FM9001 files although it is not required to replay the proof. We include it as a simple way to load all of the macro functions described in Chapter 2. If one has run the file "sydef.lisp" to completion, then, as a by-product of the run, a number of Nqthm "libraries" will have been written. It is convenient to resume the Nqthm state for any of these libraries by first loading "sysload.lisp" and then invoking `NOTE-LIB` on the desired library.

2.3 DO-FILES

This file defines a function `DO-FILES` that is used to process a sequence of event files.

See Section 14.3 for the Lisp file "do-files.lisp".

2.4 DO-EVENTS-RECURSIVE

This file defines the function `DO-EVENTS-RECURSIVE` that is used for running a list of events. In particular, this function is used in the file "monotonicity-macros.lisp".

See Section 14.4 for the Lisp file "do-events-recursive.lisp".

2.5 DISABLE

The general problem solved by these macros is to merge different event files. This file contains macros used in files "math-enable.events" and "math-disable.events" (see Sections 13.1 and 3.4) for controlling the events that are enabled at a given point. (The Nqthm-1992 command `SET-STATUS` was not available at the time these macros were written, or else they probably would not have been necessary.) If Nqthm allowed partially-ordered theories, then perhaps this sort of problem would disappear.

In particular, the file "math-enable.events" contains the following forms.

```
(better-disable-back-to b-knownp)

(enable-theory math-theory)
```

The event file to be run immediately after "math-enable.events" is the file "alu-interpretation.events", which was developed within the environment that existed just before the event `B-KNOWNP` in "approx.events". The first form above disables a number of events so that the enabled events will closely approximate those

that were enabled at the time the event `B-KNOWNP` was submitted. Then the second form enables all events in a certain theory, `MATH-THEORY`. The expectation is that the resulting environment will sufficiently approximate the one in which "alu-interpretation.events" was created so that the events in that file will run successfully.

Incidentally, the aforementioned theory `MATH-THEORY` was created much earlier in the event sequence, in the file "math-disable.events", by the use of the macro `DISABLE-BACK-TO`. In essence, that macro "saved" the current enabled state into the theory `MATH-THEORY`, for later use as discussed above.

See Section 14.5 for the Lisp file "disable.lisp".

2.6 MACROS

This file contains a number of macros used for generating events related to hardware modules. Some are summarized below.

When we represent a hardware module in the Nqthm logic, we produce several Nqthm events in a stylized manner, including the following: a module recognizer, a module generator and netlist builder, an Nqthm specification function for the module, and one or more correctness theorems for the module. In addition, some of these events are to be disabled. The macros presented below are used to reduce the effort required to construct all of these events.

First let us examine in some detail a macro that takes the name of a "hardware" specification function and produces a series of Nqthm events that it submits to the system. For example, consider the specification of a "mode" recognizer given below.

```
(defn decode-mode (op0 op1 op2 op3)
  (b-nor (b-nor3 op0 op1 op2)
         op3))
```

Given that the function `DECODE-MODE` has been defined, the macro call `(DEFN-TO--MODULE DECODE-MODE)` results in the creation of the Nqthm event forms as shown below. Note that the formal parameters of `DECODE-MODE` are each intended to be Boolean signal values, and that this function produces a single Boolean output. `DEFN-TO-MODULE` requires this "shape"; it cannot be used, for example, to produce modules with multiple outputs.

Here are the events produced by evaluating `(DEFN-TO-MODULE DECODE-MODE)`. In each case below we precede the event form with a short comment.

Define the four-valued logic specification function for this module.

```
(DEFN F$DECODE-MODE (OP0 OP1 OP2 OP3)
```

```
  (F-NOR (F-NOR3 OP0 OP1 OP2)
         OP3))
```

The specification above is to be kept disabled.

```
(DISABLE F$DECODE-MODE)
```

Define the module constant.

```
(DEFN DECODE-MODE* ()
  '(DECODE-MODE (OP0 OP1 OP2 OP3)
                (W-1)
                ((G-0 (W-0) B-NOR3 (OP0 OP1 OP2))
                 (G-1 (W-1) B-NOR (W-0 OP3)))
                NIL))
```

Define a recognizer for netlists that correctly represent this module, in terms of the module constant just defined as well as the previously defined netlist recognizers for its submodules.

```
(DEFN DECODE-MODE& (NETLIST)
  (AND (EQUAL (LOOKUP-MODULE 'DECODE-MODE NETLIST)
              (DECODE-MODE*))
       (B-NOR3& (DELETE-MODULE 'DECODE-MODE NETLIST))
       (B-NOR& (DELETE-MODULE 'DECODE-MODE NETLIST))))
```

The netlist recognizer is to be kept disabled.

```
(DISABLE DECODE-MODE&)
```

Define the netlist constant for this module so that it includes the module as well as all the netlist constants for its submodules.

```
(DEFN DECODE-MODE$NETLIST ()
  (CONS (DECODE-MODE*)
        (UNION (B-NOR3$NETLIST)
               (B-NOR$NETLIST))))
```

Prove a correctness theorem for the module. It says that if `NETLIST` correctly represents the module, then the output vector from this module is equal to the one-bit vector containing the value given by the four-valued specification function. Note that an analogous lemma would also have been proved about the new state of the module, if the module had been a state-holding module.

```
(PROVE-LEMMA DECODE-MODE$VALUE (REWRITE)
  (IMPLIES (DECODE-MODE& NETLIST)
           (EQUAL (DUAL-EVAL 0 'DECODE-MODE
                             (LIST OP0 OP1 OP2 OP3)
                             STATE NETLIST)
                  (LIST (F$DECODE-MODE OP0 OP1 OP2 OP3))))
  ((ENABLE DECODE-MODE& F$DECODE-MODE B-NOR3$VALUE B-NOR$VALUE)
   (DISABLE-THEORY F-GATES)))
```

The `VALUE` lemma above is to be kept disabled.

```
(DISABLE DECODE-MODE$VALUE)
```

The final lemma simply equates the four-value specification function with the original (input, Boolean) specification function in the case that the inputs are all Boolean.

```
(PROVE-LEMMA F$DECODE-MODE=DECODE-MODE (REWRITE)
  (IMPLIES (AND (BOOLP OP0)
                (BOOLP OP1)
                (BOOLP OP2)
                (BOOLP OP3))
           (EQUAL (F$DECODE-MODE OP0 OP1 OP2 OP3)
                  (DECODE-MODE OP0 OP1 OP2 OP3)))
  ((ENABLE BOOLP-B-GATES F$DECODE-MODE DECODE-MODE)
   (DISABLE-THEORY F-GATES B-GATES)))
```

Let us turn to brief summaries of utilities provided in this file.
`(DEFN-TO-MODULE spec &KEY value-lemma boolp-value-lemma)` has been described above. It converts simple Nqthm specifications to Nqthm events, including definitions of generators and recognizers for modules and netlists, as well as appropriate theorems. The specification argument `spec` must be the name of an Nqthm `DEFN` event whose formal parameters are each intended to be a signal, where the function's value is intended to be the module's single output value.

`(MODULE-PREDICATE generator)` writes the netlist predicate for simple modules. For example, if the module is defined by `(M*)`, then `(MODULE-PREDICATE M*)` creates `(M& NETLIST)`.

`(MODULE-NETLIST generator)` assembles the netlist for simple modules. For example, if the module is defined by `(M*)`, then `(MODULE-NETLIST M*)` creates `(M$NETLIST NETLIST)`.

`(DESTRUCTURING-LEMMA generator)` creates a lemma that explicitly states how to destructure a module definition. Because of quirks in equality reasoning, it is not effective simply to let module definitions open up. It also creates two `DISABLE`

events. For example, after defining the n-bit-wide adder `(BV-ADDER* n)`, the following macro call creates the events shown below it.

```
(destructuring-lemma bv-adder*)

(PROVE-LEMMA BV-ADDER*$DESTRUCTURE (REWRITE)
  (AND (EQUAL (CAR (BV-ADDER* N))
              (INDEX 'BV-ADDER N))
       (EQUAL (CADR (BV-ADDER* N))
              (CONS (INDEX 'CARRY 0)
                    (APPEND (INDICES 'A 0 N)
                            (INDICES 'B 0 N))))
       (EQUAL (CADDR (BV-ADDER* N))
              (APPEND (INDICES 'SUM 0 N)
                      (LIST (INDEX 'CARRY N))))
       (EQUAL (CADDDR (BV-ADDER* N))
              (BV-ADDER-BODY 0 N))
       (EQUAL (CADDDDR (BV-ADDER* N)) NIL)))

(DISABLE BV-ADDER*)

(DISABLE BV-ADDER*$DESTRUCTURE))
```

The macro call `(MODULE-GENERATOR (generator . args) name inputs outputs body state)` is used to define a module. It is followed by the events created by the macro `DESTRUCTURING-LEMMA`. `(GENERATE-BODY-INDUCTION-SCHEME generator)` creates a `(DUAL-EVAL 1 ...)` induction scheme for body generators of the form `(IF test something (CONS occurrence recursive-call))`.

The file concludes with definitions of a couple of Lisp reader macros. First, a "`#v`" reader macro is an abbreviation mechanism for reading in bit-vector constants. For example, `#v001` is read as `(LIST T F F)`. Second, a reader macro for index names for `DUAL-EVAL` netlists is defined. For example, `#i(A 10)` is read as `(INDEX 'A 10)`, and `#i(A 0 10)` is read as `(INDICES 'A 0 10)`.

See Section 14.6 for the Lisp file "macros.lisp".

2.7 EXPAND

The `EXPAND` macro is used by other utilities to generate events. What `(EXPAND form)` returns is the term that the Nqthm simplifier is expected to produce when trying to prove a lemma about `form`. For example, suppose that we submit the following form.

```
(expand '(plus (add1 x) y))
```

In that case, Nqthm returns the following answer.

```
(ADD1 (PLUS X Y))
```

The macro EXPAND-LEMMA is similar to EXPAND, but it produces a PROVE-LEMMA event that equates the input term with the result produced by EXPAND. For example, the input immediately below causes the PROVE-LEMMA event below it to be submitted to the theorem prover.

```
(expand-lemma plus-add1-first-arg (rewrite)
              nil
              (plus (add1 x) y))

(PROVE-LEMMA PLUS-ADD1-FIRST-ARG (REWRITE)
  (EQUAL (PLUS (ADD1 X) Y)
         (ADD1 (PLUS X Y))) NIL)
```

See Section 14.7 for the Lisp file "expand.lisp".

2.8 VECTOR-MACROS

This file defines a single Lisp macro, VECTOR-MODULE. It is similar in spirit to the macro DEFN-TO-MODULE discussed earlier in Section 2.6, in that it generates Nqthm events from a higher-level specification of a module. Perhaps the simplest way to explain what it does is to show how this macro works on an example. Suppose that we have defined a module B-BUF that buffers a single input line into a single output line, and we want to create a vector version that has an arbitrary number n of input lines and has n output lines, by connecting n B-BUF modules in parallel. For example, for $n = 3$ we might want to obtain something like the following module.

```
'(V-BUF_3 (A_0 A_1 A_2)
          (Y_0 Y_1 Y_2)
          ((G_0 (Y_0) B-BUF (A_0))
           (G_1 (Y_1) B-BUF (A_1))
           (G_2 (Y_2) B-BUF (A_2)))
          NIL)
```

The following call of the macro `VECTOR-MODULE` creates the module shown above. More precisely, if we apply the function `LISP-NETLIST` (see Section 5.9) to the module created by the call of `VECTOR-MODULE` shown below then we obtain the module displayed above. Here is how this macro call expands; a quick glance should give a rough idea of what is going on, so we eschew further comments.

```
(macroexpand
 '(VECTOR-MODULE v-buf    ;the name of a parametrized module
                 (g (y) b-buf (a))
                 ((v-threefix a))
                 :enable (f-buf)))

(PROGN

 (DEFN V-BUF$BODY (M N)
   (IF (ZEROP N) NIL
       (CONS (LIST (INDEX 'G M) (LIST (INDEX 'Y M)) 'B-BUF
                   (LIST (INDEX 'A M)))
             (V-BUF$BODY (ADD1 M) (SUB1 N)))))

 (DISABLE V-BUF$BODY)

 (MODULE-GENERATOR (V-BUF* N) (INDEX 'V-BUF N) (INDICES 'A 0 N)
                   (INDICES 'Y 0 N) (V-BUF$BODY 0 N) NIL)

 (DEFN V-BUF& (NETLIST N)
   (AND (EQUAL (LOOKUP-MODULE (INDEX 'V-BUF N) NETLIST)
               (V-BUF* N))
        (B-BUF& (DELETE-MODULE (INDEX 'V-BUF N) NETLIST))))

 (DISABLE V-BUF&)

 (DEFN V-BUF$NETLIST (N) (CONS (V-BUF* N) (B-BUF$NETLIST)))

 (PROVE-LEMMA V-BUF$UNBOUND-IN-BODY (REWRITE)
   (IMPLIES (LESSP L M)
            (UNBOUND-IN-BODY (INDEX 'Y L) (V-BUF$BODY M N)))
   ((ENABLE V-BUF$BODY UNBOUND-IN-BODY)))

 (DISABLE V-BUF$UNBOUND-IN-BODY)

 (PROVE-LEMMA V-BUF$BODY-VALUE (REWRITE)
   (IMPLIES (AND (B-BUF& NETLIST) (EQUAL BODY (V-BUF$BODY M N)))
```

```
           (EQUAL (COLLECT-VALUE (INDICES 'Y M N)
                                 (DUAL-EVAL 1 BODY BINDINGS
                                            STATE-BINDINGS
                                            NETLIST))
                  (V-THREEFIX
                   (COLLECT-VALUE (INDICES 'A M N) BINDINGS))))
  ((INDUCT (VECTOR-MODULE-INDUCTION BODY M N BINDINGS
                                    STATE-BINDINGS NETLIST))
   (DISABLE-THEORY F-GATES)
   (ENABLE V-BUF$BODY B-BUF$VALUE V-BUF$UNBOUND-IN-BODY V-THREEFIX
           F-BUF)))

(DISABLE V-BUF$BODY-VALUE)

(PROVE-LEMMA V-BUF$VALUE (REWRITE)
  (IMPLIES (AND (V-BUF& NETLIST N)
                (AND (PROPERP A) (EQUAL (LENGTH A) N)))
           (EQUAL (DUAL-EVAL 0 (INDEX 'V-BUF N) A STATE NETLIST)
                  (V-THREEFIX A)))
  ((ENABLE V-BUF& V-BUF$BODY-VALUE V-BUF*$DESTRUCTURE)))

(DISABLE V-BUF$VALUE)

)
```

See Section 14.8 for the Lisp file "vector-macros.lisp".

2.9 PRIMP-DATABASE

This file defines the Lisp constant `COMMON-LISP-PRIMP-DATABASE`, which is used in some Lisp macros as well as in the definition of the Nqthm constant (i.e., 0-ary function) `PRIMP-DATABASE`. This constant is a list that represents the primitive modules in our hardware description language. Each entry in this list may be viewed as a record whose fields describe properties of a given primitive module.

Let us examine one such entry: the entry for the Boolean two-input *and* gate. We include a comment in front of each field.

```
(b-and

 ;;  These are the slope and intercept delays for LSI Logic's
 ;;  implementation of this module.
 (delays        ((144 422) (54 707)))
```

```
;;  The module can drive 10 standard loads.  This is used for
;;  crude estimates of fan-out restrictions.  The more accurate
;;  estimates are given by the  delays field shown just above.
(drives         10)

;;  Each of the inputs is expected to be Boolean.
(input-types    boolp boolp)

;;  The inputs are named  a and  b.
(inputs         a b)

;;  The standard input loads are both 1.
(loadings       1 1)

;;  The name of the corresponding LSI Logic model is  an2.
(lsi-name       . an2)

;;  The output(s) combinationally depend on both inputs.
(out-depends    (a b))

;;  There is a single Boolean output.
(output-types   boolp)

;;  The output name is  z.
(outputs        z)

;;  The vector of outputs from this device contains the single
;;  value obtained by "evaluating" the indicated Nqthm term.
(results        . (cons (f-and a b) 'nil))

;;  The remaining fields are intended to approximately measure
;;  the "cost" of the primitive.
(gates          . 2)
(primitives     . 1)
(transistors    . 6))
```

For state-holding modules we have some additional fields. For example, the basic single-bit D flip-flop device FD1 has the following additional fields in its entry.

```
;;  The new state is obtained by "evaluating" the indicated
```

```
;;  Nqthm term.
(new-states     . (f-buf d))

;;  The state is a single Boolean value.
(state-types    . boolp)

;;  The name of the state is  state.
(states         . state)
```

See Section 14.9 for the Lisp file "primp-database.lisp".

2.10 PRIMITIVES

This file contains functions and macros to automate the creation of DUAL-EVAL lemmas for the primitives. For each primitive listed in our primitive database (see Section 2.9), a series of lemmas is proven that describes the effect of the DUAL-EVAL simulator on each language primitive.

See Section 14.10 for the Lisp file "primitives.lisp".

2.11 CONTROL-LISP

This file defines a number of macros that are used to define the control logic in Section 10.3. We defer explanation of these macros until that section.

See Section 14.11 for the Lisp file "control.lisp".

2.12 EXPAND-FM9001

This file defines a number of macros that write lemmas about the transitions between the major FM9001 control states. There are also some definitions used to compute the amount of time required for the various instruction types. These macros are used by the event file "expand-fm9001.events" (Section 11.1).

See Section 14.12 for the Lisp file "expand-fm9001.lisp".

2.13 MONOTONICITY-MACROS

The Lisp utilities in this file are used in the event file "approx.events"; see Section 11.3 for further discussion.

See Section 14.13 for the Lisp file "monotonicity-macros.lisp".

2.14 TRANSLATE

This file contains a Common Lisp program that translates netlists from the `DUAL--EVAL` hardware description language into NDL, LSI Logic's Network Description Language. We used this program to produce the FM9001 netlist which was delivered to LSI Logic and subsequently used by them to manufacture working FM9001 microprocessors. The FM9001 netlist is presented in Chapter 15. The initial comment in the file "translate.lisp" describes how to print netlists, including the one used for the FM9001.

The Common Lisp code in this file has not been subjected to any form of verification with Nqthm-1992. However, the printing process is a very straightforward translation and occupies only about two pages of text. To validate the correctness of our translation process, we simulated the converted netlist using LSI Logic's simulator `lsim` and checked to see that `lsim` produced the same answers using a variety of test vectors.

See Section 14.14 for the Lisp file "translate.lisp".

2.15 PURIFY

This file defines the Lisp utility `LIBRARY-TO-EVENTS`, which converts an Nqthm or Pc-Nqthm library that may have been created in an environment containing many "unofficial" Lisp macros or even redefinitions of Nqthm functions into a single Nqthm event file whose syntax is acceptable to the `PROVE-FILE` function of Nqthm-1992. Since `PROVE-FILE` is very careful in what it accepts as valid Nqthm input, this approach gives us added confidence in the theorems that we claim to have proved.

The exact approach is as follows.

1. Start up Nqthm and submit the form
   `(LOAD "sysdef.lisp")`
   — this creates the "proofs" library.

2. Submit the form
   `(library-to-events "fm9001")`.

The file `fm9001-replay.events` is thereby created. To run this single file one may then submit the form:

```
(prove-file-out "fm9001-replay")
```

Chapter 3

SOME ARITHMETIC LIBRARIES

3.1 BAGS

This file defines the BAGS theory, which provides rewrite rules about bags, i.e., multi-sets. Bags are represented by lists and are manipulated by the following five functions: DELETE, BAGDIFF, BAGINT, OCCURRENCES, and SUBBAGP. A theory BAGS is defined that contains a number of rewrite rules about these functions.

See Section 14.16 for the event file "bags.events".

3.2 NATURALS

This file defines several theories for reasoning about natural numbers, which are gathered together into a single NATURALS theory at the end of the file.

```
(deftheory naturals
  (addition
   multiplication
   remainders
   quotients
   exponentiation
   logs
   gcds))
```

Here is a brief description of the events in this file, adapted from Bevier's hardware library [3]. Some of the ideas are analogous to ideas in the integers library, which are given a more thorough explanation below.

The first part of the development of our arithmetic library is devoted to rules which canonicalize terms involving `PLUS` and `DIFFERENCE`. Rewrite rules canonicalize terms involving these two functions into "preferable" forms. For instance, `DIFF-DIFF-ARG1` canonicalizes a `DIFFERENCE` expression whose first argument is a `DIFFERENCE`.

Lemma. `DIFF-DIFF-ARG1`

```
(equal (difference (difference x y) z)
       (difference x (plus y z))))
```

The lemmas about `TIMES`, `REMAINDER` and `QUOTIENT` have been distilled from Boyer and Moore's 1979 book [5], together with the proof of FM8501 [13], [14] and the proof of Kit [2], [4].

See Section 14.17 for the event file "naturals.events".

3.3 INTEGERS

This file defines the `INTEGERS` theory for reasoning about integers. The following functions are defined: `INTEGERP`, `FIX-INT`, `IZEROP`, `ILESSP`, `ILEQ`, `IPLUS`, `INEG`, `IDIFFERENCE`, `IABS`, `ITIMES`, `IQUOTIENT`, `IREMAINDER`, `IDIV`, `IMOD`, `IQUO`, `IREM`, and `SUBSETP`.

The rest of this section is taken largely from [17] and explains some features of this library, especially its metalemmas. This library has evolved over the years, starting with the test suite for the Boyer-Moore prover, continuing to evolve in the dissertations of Hunt [13] and Bevier [2], and reaching the present form (at least approximately) with Kaufmann [17]. It has been designed so that one can use it profitably without reading further. We do, however, present some ideas on how better to take advantage of the library. For example, it is suggested that one may want to experiment by enabling the rewrite rule `ILESSP-TRICHOTOMY`.

The first section below briefly summarizes the basic integer functions and some rewrite rules defined in this library. The second section states the metalemmas and describes the algorithms they implement, and suggests possible actions on the part of the user to adjust the set of metalemmas that are enabled. The final section has some miscellaneous caveats and suggestions.

3.3.1 Basics

The basic functions defined in this library are defined in terms of natural number functions, and have been put into the following theory.

```
(deftheory all-integer-defns
  (integerp fix-int izerop ilessp ileq iplus ineg idifference
```

```
           iabs itimes iquotient iremainder idiv imod iquo irem))
```

In accordance with the usual way arithmetic functions are defined in Nqthm, these functions act as though non-integer arguments are coerced to `0`. The history has been left in a state where integer functions (e.g., `ILESSP`, `FIX-INT`, `IPLUS`, ...) have been disabled, with three exceptions: `IZEROP`, `ILEQ`, and `IDIFFERENCE`. Therefore, there are very few rules about `IZEROP` (but plenty of rules about `FIX-INT`), few rules about `ILEQ` (but many rules about `ILESSP`), and few rules about `IDIFFERENCE` (but many about `IPLUS` and `INEG`). If one wants to prove a basic integer fact by opening up functions that are normally disabled, an `(ENABLE-THEORY INTEGER-DEFNS)` hint should be given, where `INTEGER-DEFNS` is defined as follows.

```
(deftheory integer-defns
  (integerp fix-int ilessp iplus ineg iabs itimes
            iquotient iremainder idiv imod iquo irem))
```

Let us turn briefly to rewrite rules. There are rewrite rules expressing the commutativity and associativity of `IPLUS` and `ITIMES`. (Notice that for the metalemmas, it suffices to deal with terms that are right-associated with respect to these operations.) Also included are distributive laws that push `IPLUS` out of `ITIMES` expressions and out of `INEG` expressions and that push `INEG` out of `ITIMES` expressions. Rules have been proved which state that `0` and `1` are the respective identities for integer addition (i.e., `IPLUS`) and integer multiplication (i.e., `ITIMES`). There are also a number of trivial "type" rules, e.g., `IPLUS` always returns an integer and implicitly applies `FIX-INT` to its arguments. Finally, there are rules for combining constants in `IPLUS` terms, so that for example `(IPLUS 3 (IPLUS X 7))` is rewritten to `(IPLUS 10 X)`, `(EQUAL (IPLUS 10 X) (IPLUS Z 3))`, which is then rewritten to `(EQUAL (IPLUS 7 X) (FIX-INT Z))`, and finally `(ILESSP (IPLUS 3 Z) (IPLUS 10 X))` is rewritten to `(NOT (ILESSP (IPLUS 6 X) Z))`. Here are the lemmas used (besides commutativity) in these respective examples:

```
Theorem. IPLUS-CONSTANTS
(equal (iplus (add1 i) (iplus (add1 j) x))
       (iplus (plus (add1 i) (add1 j)) x))
```

```
Theorem. CANCEL-CONSTANTS-EQUAL
(equal (equal (iplus (add1 i) x)
              (iplus (add1 j) y))
       (if (lessp i j)
           (equal (fix-int x)
                  (iplus (difference j i) y))
           (equal (iplus (difference i j) x)
                  (fix-int y))))

Theorem. CANCEL-CONSTANTS-ILESSP
(equal (ilessp (iplus (add1 i) x)
               (iplus (add1 j) y))
       (if (lessp i j)
           (not (ilessp (iplus (sub1 (difference j i)) y)
                        x))
           (ilessp (iplus (difference i j) x)
                   y)))
```

It had seemed that metalemmas might be needed for dealing with such constants, but in fact numeric constants are lower in the Nqthm term order than terms with variables, so commutativity and associativity of `IPLUS` tend to push constants to the front of the sum.

3.3.2 Metalemmas

The reader is referred to the events list for the definitions of the relevant meta-functions. Here we simply state the metalemmas and make a few comments about them.

The first metalemma cancels pairs `V` and `(INEG V)` in a given sum. The idea of `CANCEL-INEG` is that it when it sees a sum `(IPLUS x y)`, it looks to see if the formal negative of `x` appears as a summand of `y`, where by the "formal negative" of `x` we mean `(INEG x)` unless `x` is of the form `(INEG x1)`, in which case we mean `x1`. If so, then `CANCEL-INEG` cancels that pair.

```
Theorem. CORRECTNESS-OF-CANCEL-INEG
(equal (eval$ t x a)
       (eval$ t (cancel-ineg x) a)))
```

The next two metalemmas are for cancelling common summands on both sides of an equality or inequality (respectively). There are no particular surprises here. Notice that since the function symbol `ILEQ` is kept enabled, there is no need for a corresponding cancellation lemma for `ILEQ`.

```
Theorem. CORRECTNESS-OF-CANCEL-IPLUS
(equal (eval$ t x a)
       (eval$ t (cancel-iplus x) a))

Theorem. CORRECTNESS-OF-CANCEL-IPLUS-ILESSP
(equal (eval$ t x a)
       (eval$ t (cancel-iplus-ilessp x) a))
```

The next two metalemmas are useful for automatically cancelling factors on both sides of an equation or inequality, respectively. The factors must be explicit, however. So for example, the first of these lemmas below will simplify the expression

```
(equal (itimes x y) (itimes x z))
```

to

```
(if (equal (fix-int x) 0)
    t
  (equal (fix-int y) (fix-int z)))
```

But it will not simplify the expression `(EQUAL (IPLUS (ITIMES X Y) X) (IPLUS X (ITIMES X Z)))`. Therefore, there are stronger versions of these metalemmas, namely the third and fourth lemmas below (which strengthen the first and second, respectively). Because these last two are stronger, the first two are actually disabled in this library. If one finds these last two to be a nuisance for some reason, however (e.g., if they are too slow), it is of course easy enough to disable the last two and enable the first two. It seems so far that perhaps very little speed is sacrificed by having the latter pair enabled instead of the former.

```
Theorem. CORRECTNESS-OF-CANCEL-ITIMES (disabled)
(equal (eval$ t x a)
       (eval$ t (cancel-itimes x) a))

Theorem. CORRECTNESS-OF-CANCEL-ITIMES-ILESSP (disabled)
(equal (eval$ t x a)
       (eval$ t (cancel-itimes-ilessp x) a))

Theorem. CORRECTNESS-OF-CANCEL-ITIMES-FACTORS
(equal (eval$ t x a)
       (eval$ t (cancel-itimes-factors-expanded x) a))

Theorem. CORRECTNESS-OF-CANCEL-ITIMES-ILESSP-FACTORS
(equal (eval$ t x a)
```

```
       (eval$ t (cancel-itimes-ilessp-factors x) a))
```

Remark. Notice that the metalemma CORRECTNESS-OF-CANCEL-ITIMES-FACTORS refers to the metafunction CANCEL-ITIMES-FACTORS-EXPANDED. There is in fact a function CANCEL-ITIMES-FACTORS, but it has seemed possible to gain efficiency by expanding all occurrences of AND and OR in the body of this function, since the executable counterparts of AND and OR are not "lazy" in Nqthm. (Preliminary tests suggests only slight gains in efficiency, however.) The Lisp macro NQTHM-MACROEXPAND, whose definition appears in a comment in the events below, was used to create the expanded version CANCEL-ITIMES-FACTORS-EXPANDED automatically. Some other metafunction definitions have been similarly created. The following rule, followed by (DISABLE CANCEL-ITIMES-FACTORS-EXPANDED), eliminates the need to reason about the "expanded" function CANCEL-ITIMES--FACTORS-EXPANDED:

```
Theorem. CANCEL-ITIMES-FACTORS-EXPANDED-CANCEL-ITIMES-FACTORS
(equal (cancel-itimes-factors-expanded x)
       (cancel-itimes-factors x))
```

Our final group of metalemmas takes care of some details not handled by the metalemmas above. The first of these, CORRECTNESS-OF-CANCEL-FACTORS-0, replaces a term that equates a product with 0 by the disjunction of the assertions saying that some factor equals 0. (More precisely, each disjunct says that FIX-INT applied to the factor equals 0.) The product can in fact be implicit, for as the following example shows, the function CANCEL-FACTORS-0 implicitly factors the expression completely.

```
(cancel-factors-0
 '(equal '0 (itimes z (iplus x (itimes x y)))))

  =

'(OR (EQUAL (FIX-INT Z) '0)
     (OR (EQUAL (FIX-INT (IPLUS '1 Y)) '0)
         (EQUAL (FIX-INT X) '0)))
```

Here then are the metalemmas that apply when a product is set equal to (or less than, or greater than) 0.

```
Theorem. CORRECTNESS-OF-CANCEL-FACTORS-0
```

```
(equal (eval$ t x a)
       (eval$ t (cancel-factors-0 x) a))

Theorem. CORRECTNESS-OF-CANCEL-FACTORS-ILESSP-0
(equal (eval$ t x a)
       (eval$ t (cancel-factors-ilessp-0 x) a))
```

Finally, there are metalemmas for removing INEG terms from equations and inequalities. The desirability of performing such normalizations is illustrated by the following example:

```
(implies (equal (iplus x y)
                (iplus u v))
         (equal (fix-int x)
                (iplus u (idifference v y))))
```

Without the first metalemma below, the integer library fails to prove this obvious fact. However, the system may use that metalemma by replacing the term

```
(equal (fix-int x)
       (iplus u (iplus v (ineg y))))
```

with the term

```
(if (integerp (fix-int x))
    (equal (iplus y (fix-int x))
           (iplus u v))
    f)
```

which in turn simplifies to the hypothesis of the original implication. Here then are those final two metalemmas.

```
Theorem. CORRECTNESS-OF-CANCEL-INEG-TERMS-FROM-EQUALITY
(equal (eval$ t x a)
       (eval$ t (cancel-ineg-terms-from-equality-expanded x) a))

Theorem. CORRECTNESS-OF-CANCEL-INEG-TERMS-FROM-INEQUALITY
(equal (eval$ t x a)
       (eval$ t (cancel-ineg-terms-from-inequality-expanded x) a))
```

These last two metalemmas do *not* subsume the first one, CORRECTNESS-OF--CANCEL-INEG. For, these lemmas only apply to INEG terms that occur as a summand of the left or right side of an equation or inequality, while CORRECTNESS-OF--CANCEL-INEG cancels negatives in arbitrary sums.

3.3.3 Caveats

Here are a few things to watch out for when using this library. There are probably many others.

First of all, a previous version of the integers library had more power for reasoning about terms in which integer functions are applied to arguments that are not known to be integers. For example, the following rewrite rule IPLUS-LEFT-ID is now disabled.

```
(implies (not (integerp x))
         (equal (iplus x y)
                (fix-int y)))
```

Here is a list of other such rules about non-integers that have been left disabled: INEG-OF-NON-INTEGERP, IPLUS-RIGHT-ID, NOT-INTEGERP-IMPLIES-NOT-EQUAL--IPLUS, IPLUS-LEFT-ID, NOT-INTEGERP-IMPLIES-NOT-EQUAL-ITIMES. These rules have been disabled because one can pay a rather severe performance penalty otherwise. The example lemma FOUR-SQ shown below created a time triple of [0.1 62.4 0.2] on a Sun3/60 with the integer library loaded; but when the above rules were first enabled, the time triple was instead [0.1 84.9 0.2]. Two related rules that have also been left disabled to avoid backchaining are ITIMES-ZERO1 and ITIMES-ZERO2. Here is the former of those:

```
(implies (equal (fix-int x) 0)
         (equal (itimes x y) 0))
```

With those two rules enabled in addition to the five listed above, the proof of this example took time [0.1 797.6 0.3]! These rules are not too important anyhow, given the metalemma CORRECTNESS-OF-CANCEL-FACTORS-0. A more difficult case is the following rewrite rule, named SAME-FIX-INT-IMPLIES-NOT-ILESSP.

```
(implies (equal (fix-int x) (fix-int y))
         (not (ilessp x y)))
```

Perhaps it would be better to leave this rule enabled, but it has been disabled. Another such potentially useful rewrite rule that is kept disabled is the following, named IZEROP-ILESSP-0-RELATIONSHIP.

```
(equal (equal (fix-int x) 0)
       (and (not (ilessp x 0))
            (not (ilessp 0 x))))
```

The following rewrite rule ILESSP-TRICHOTOMY is kept disabled, though it is sometimes very useful to enable this rule.

```
(implies (not (ilessp x y))
         (equal (ilessp y x)
                (not (equal (fix-int x) (fix-int y)))))
```

If both IZEROP-ILESSP-0-RELATIONSHIP and ILESSP-TRICHOTOMY are enabled, one is in extreme danger of entering an infinite loop in the rewriter! In fact there is a note in the event list below suggesting that this rule caused trouble in the proof of CORRECTNESS-OF-CANCEL-ITIMES-ILESSP-FACTORS.

Here is the test problem mentioned above, which was suggested by William Pase of Odyssey Research Associates.

```
Definition.
(square x) =
(itimes x x)

Definition.
(four-squares a b c d) =
(iplus (square a)
       (iplus (square b)
              (iplus (square c)
                     (square d))))

Theorem. FOUR-SQ
(equal (itimes (four-squares a b c d)
               (four-squares r s t0 u))
       (four-squares
        (iplus (itimes a r)
               (iplus (itimes b s)
                      (iplus (itimes c t0)
                             (itimes d u))))
```

```
(iplus (itimes a s)
       (iplus (ineg (itimes b r))
              (iplus (itimes c u)
                     (ineg (itimes d t0)))))
(iplus (itimes a t0)
       (iplus (ineg (itimes b u))
              (iplus (ineg (itimes c r))
                     (itimes d s))))
(iplus (itimes a u)
       (iplus (itimes b t0)
              (iplus (ineg (itimes c s))
                     (ineg (itimes d r)))))))
```

See Section 14.18 for the event file "integers.events".

3.4 MATH-DISABLE

This file disables appropriate lemmas. See Section 2.5 for more details.

See Section 14.19 for the file "math-disable.events".

Chapter 4

SOME FUNDAMENTAL NOTIONS

This chapter introduces some basic lemmas and definitions that are used throughout this work, including some rewrite rules for numbers and lists, the `INDEX` shell for creating indexed names, lookup functions, basic Boolean and four-valued logic functions, constructors for manipulating the machine's memory, and some basic tree-oriented functions.

This chapter also introduces our four-valued logic, which has the values `T` (Boolean "true"), `F` (Boolean "false"), `(Z)` (a high impedance, intermediate value), and `(X)` (unknown). The function `FOURP` is a recognizer for these four values, i.e., it returns `T` on each of the four values above and `F` on everything else. The function `FOURFIX` returns its argument unchanged if its argument is a four-valued logic value (i.e., a `FOURP`), and otherwise returns `(X)`; in other words, `FOURFIX` can be viewed as a coercion function that coerces all Nqthm objects that are not four-valued logic values to the value `(X)`, i.e., unknown. There are analogous functions `THREEP` and `THREEFIX` for a three-valued logic that excludes `(Z)`, as well as `BOOLP` and `BOOLFIX` for ordinary two-valued Boolean logic based on `T` and `F`.

4.1 INTRO

The file "intro.events" contains a number of basic definitions and lemmas for arithmetic, lists, and trees.

First we define functions `IF*`, `OR*`, `AND*`, and `NOT*`, which are really the same as their "unstarred" counterparts, but give us finer control over the theorem prover when we need it. The problem with the built-in propositional functions is that the theorem prover has some heuristics for them that we sometimes prefer to override. Along the same lines, we prove some trivial lemmas such as `CAR-CDR-IF-CONS` that help the theorem prover in its treatment of `IF` expressions.

The arithmetic lemmas that come next are in some cases subsumed by the natural number library (see Section 3.2), but these were proved in isolation before we incorporated those libraries into our work. For example, the following lemma tells the Boyer-Moore prover to use the fact that the sum of two natural numbers is zero if and only if both of those numbers are zero.

```
(equal (equal (plus a b) 0)
       (and (zerop a) (zerop b)))
```

The files also define a number of list and tree processing functions, along with rewrite rules that support their use. For instance, we define the following function that returns all but the first `N` elements of a given list `L`.

Definition.

```
(restn n l)
 =
(if (listp l)
    (if (zerop n)
        l
      (restn (sub1 n) (cdr l)))
  l)
```

Here is an example of a rewrite rule about lists. It simplifies the application of `RESTN` to a list that is formed by the built-in list concatenation function, `APPEND`.

```
(equal (restn n (append a b))
       (append (restn n a)
               (restn (difference n (length a)) b)))
```

See Section 14.20 for the event file "intro.events".

4.2 LIST-REWRITES

The lemmas in this file were useful for very technical reasons, probably not worth going into here beyond the comments in the file "list-rewrites.events".

See Section 14.21 for the event file "list-rewrites.events".

4.3 INDICES

These events define the `INDEX` shell constructor to help us create `DUAL-EVAL` netlists. For example, the term `(INDEX 'G 3)` is a legitimate Nqthm term, which we think of intuitively as G_3. In fact, the index reader (see Section 2.6) tells the Lisp reader to read

```
#i(A 3)
```

exactly as though it were

```
(INDEX 'A 3)
```

The function `INDICES` is also defined here. It can be used to create a list of `INDEX` terms, and terms formed with the `#i` reader macro are read as `INDICES` terms when the list following `#i` has three elements instead of two. The following example should make this clear: `5` is the starting index and `3` is the number of elements in the list.

```
#i(A 5 3)
```

is read the same as

```
(INDICES 'A 5 3)
```

which in turn is provably equal to

```
(LIST (INDEX 'A 5)
      (INDEX 'A 6)
      (INDEX 'A 7))
```

Thus, `#i(A 5 3)` is equal to the list of length `3` consisting of index expressions built from `'A`, starting with an "index" of `5` and continuing with successively larger "indices".

The file also has a number of lemmas about the function `INDICES`, for example that the resulting list has no duplicates.

See Section 14.22 for the event file "indices.events".

4.4 HARD-SPECS

This file defines functions for the four-valued logic used through the FM9001 proof (see Chapter 1), as well some basic Boolean and vector functions and some simple functions used in specifications. It also contains basic theorems about these functions.

Among the Boolean functions defined in this file are `B-NOT`, which is just negation, and `B-BUF`, which is the identity except that non-Boolean values are coerced to `T`. Thus, `B-BUF` is actually the same as `BOOLFIX`. Another example is `B-AND3`, which returns the logical AND of three values. Other n-ary Boolean functions (for other arities n and basic Boolean functions) are also defined, as are some basic functions for "compound gates," such as the following:

Definition.
```
(ao2 a b c d)
 =
(b-nor (b-and a b) (b-and c d))
```

The function `BVP` is among the "vector functions" defined here; it returns `T` if and only if its argument is a *bit vector*, i.e., a proper (null-terminated) list of Booleans. There are also "extensions" of the basic Boolean functions to bit vectors. For example, `V-AND` is the bit-wise `AND` of two bit-vectors. Shifting and multiplexing functions are also defined.

Some important functions to be used later in specifications are defined here. For example, the function `V-TO-NAT` converts a bit vector to a corresponding natural number, while the function `NAT-TO-V` goes the other direction by taking a natural number and a given width, producing a corresponding bit vector of that width. The function `V-ZEROP` recognizes those bit vectors whose bits are all `F`. A ripple-carry adder is specified with the recursive definition `V-ADDER`.

Finally, a number of rewrite rules are proved about the functions in this file. For example, the lemma `LENGTH-OF-V-ADDER` says that the length of the `V-ADDER` sum of a carry bit with two bit vectors is one more than the length of the first bit vector. Under "normal" circumstances we would expect the two bit-vector arguments of `V-ADDER` to have the same length, but in fact the definition of `V-ADDER` is such that the length of the result depends solely on the length of the *first* bit-vector input.

See Section 14.23 for the event file "hard-specs.events".

4.5 VALUE

This file defines two very important functions. `VALUE` returns the first value of a key in an association list. For example,

```
(VALUE 'B '((A . 3) (B . 4) (C . 5) (B . 6)))
```

is equal to 4. The other function is `COLLECT-VALUE`, which collects up the `VALUE`s of a list of keys and returns these values in the corresponding order. For example,

```
(COLLECT-VALUE '(C A B) '((A . 3) (B . 4) (C . 5) (B . 6)))
```

is equal to the list

```
'(5 3 4)
```

The file also contains a number of rewrite rules about these functions. For example, the length of `(COLLECT-VALUE ARGS ALIST)` is proved to be equal to the length of `ARGS`. The utility of some lemmas is less obvious. The following one is perhaps a bit subtle; it instructs the rewriter to attempt to show that the two "alist" arguments are equal when trying to prove the equality of two `COLLECT-VALUE` terms.

Theorem. `EQUAL-COLLECT-VALUE-PROMOTE-ALISTS`

```
(implies
 (equal alist1 alist2)
 (equal (equal (collect-value args alist1)
               (collect-value args alist2))
        t))
```

See Section 14.24 for the event file "value.events".

4.6 MEMORY

The physical implementation of the FM9001 does not include the external memory. However, we do model the memory in the top-level netlist that we reason about. Our memory is modeled using tree structures, with values stored at the tips. In this file we define basic read and write operators for such memories. The memory model presented here is specialized in later files to axiomatize both the register file and the external memory of the FM9001; see Section 4.7 and Section 4.8, respectively.

Memory is modeled in the Nqthm logic by using three shells: the shell constructor `ROM` tags read-only locations of the memory, while the shell constructor `RAM` tags read-write locations and `STUB` represents "unimplemented" portions. The present file contains these shell definitions as well as definitions of functions for reading

from and writing to memory and lemmas about these operations. For example, the lemma `NOT-V-IFF-V-ADDR1-V-ADDR2-READ-MEM1-WRITE-MEM1` says that if we perform a write operation before reading the memory, then the write has no effect on the read as long as the write address is different from the read address.

See Section 14.25 for the event file "memory.events".

4.7 DUAL-PORT-RAM

The functions `DUAL-PORT-RAM-VALUE` and `DUAL-PORT-RAM-STATE` define the current outputs and next state of the FM9001 register file. These functions are used in the behavioral specification of the FM9001 register-file primitive in the semantics in our hardware description language. There are comments in the file that describe some of the subtleties in these definitions.

See Section 14.26 for the event file "dual-port-ram.events".

4.8 FM9001-MEMORY

This file contains the specification of the FM9001 external memory. Functions for the outputs and next state of the external memory are defined, analogously to those for the register file in the preceding section, Section 4.7. This behavioral specification is more complicated than the one for the register file because it requires that a specific protocol be used when accessing the memory. For instance, we require that the address lines remain stable during read and write operations.

See Section 14.27 for the event file "fm9001-memory.events".

4.9 TREE-NUMBER

The function `TREE-NUMBER` is used to create indices that are used in the definitions of some of the circuit generator functions. In particular, when we recursively generate circuits, this function is called on to produce module names.

See Section 14.28 for the event file "tree-number.events".

4.10 F-FUNCTIONS

This file can be viewed as a follow-up to the definitions in the file "hard-specs.events" (see Section 4.4), in the sense that it provides more functions and lemmas related to the four-valued logic. Moreover, it contains rules for expanding and reducing calls to these functions in various special cases—e.g., when one or more arguments are known to be Boolean.

The functions defined are mainly the standard logical operators in the underlying four-valued logic. For example, the function `F-AND` is defined to return `T` if

its two inputs are both `T`, `F` if either of its two inputs is `F`, and the 'unknown' value `(X)` otherwise. In general, these functions "fix" their values to one of `T`, `F`, or `(X)`. However, there are two special functions `FT-BUF` and `FT-WIRE` that may return the floating or `(Z)` value. These are intended for modeling tri-state logic.

The following functions are defined: `F-BUF`, `F-AND`, `F-AND3`, `F-AND4`, `F-NOT`, `F-NAND`, `F-NAND3`, `F-NAND4`, `F-NAND5`, `F-NAND6`, `F-NAND8`, `F-OR`, `F-OR3`, `F-OR4`, `F-NOR`, `F-NOR3`, `F-NOR4`, `F-NOR5`, `F-NOR6`, `F-NOR8`, `F-XOR`, `F-XOR3`, `F-EQUV`, `F-EQUV3`, `F-IF`, `FT-BUF`, `FT-WIRE`, `F-PULLUP`. These functions are generally used to define the semantics of the primitive operators of our hardware description language.

In addition, this file contains a number of lemmas related to these functions. For example, the lemma `EXPAND-F-FUNCTIONS` (which is usually disabled) asserts the equality of each f-function call to its body. This permits the call to be opened up by the Nqthm rewriter when proving low-level facts about the four-valued logical operators. Also included are various special rewrite rules encoding various standard Boolean reductions; an example is `F-AND-REWRITE` rewriting `(F-AND F X)` to `F`.

One function given special attention in this file is `F-BUF`. It is used to define the semantics of the buffer primitives. It is a unary function that "fixes" its input to one of `T`, `F`, or `(X)`. For Boolean inputs, it is a no-op. There are various rewrite rules encoding properties of `F-BUF`.

The four-valued functions all reduce to standard Boolean operators when their arguments are Boolean. This is captured in a collection of lemmas, such as `F-GATES=B-GATES`. These provide rewrite rules that replace four-valued logic functions such as `F-NOT` with the corresponding Boolean logic functions such as `B-NOT` when the inputs are known to be Boolean.

Finally, each of the four-valued functions has a corresponding bit-vector version. These functions are defined—mapping the bit function over the input lists—and various helpful lemmas are proved.

See Section 14.29 for the event file "f-functions.events".

Chapter 5

THE SYNTAX AND SEMANTICS OF OUR HARDWARE DESCRIPTION LANGUAGE

Here we introduce the function `DUAL-EVAL`, which gives an operational (simulator) style semantics for our hardware description language, together with recognizers for well-formed netlists in this language. This chapter concludes with the function `LISP-NETLIST` that makes our mechanically-generated netlist descriptions more readable.

5.1 DUAL-EVAL

A module in our HDL is a representation of a hardware circuit design. Conceptually, the *meaning* of the module is the computation performed by that circuit for given inputs. This is formalized operationally by a collection of functions that *simulate* circuit modules for specific values of the input variables, and produce the appropriate values for the outputs and state. These interpreter functions give meaningful values only for well-formed circuit descriptions. Our syntactic constraints assure that a well-formed circuit module body has its occurrences ordered such that the outputs can be computed efficiently.

It is useful to imagine taking snapshots of a given circuit right around the rising edge of each clock cycle. In this model, the values on the circuit's wires will have

been stable for at least a little while before that edge, including the primary inputs. In particular, the output wires have achieved values during the clock cycle and can be "photographed" just before the clock ticks. The state-holding devices—latches, register file, and memory—are updated very shortly after the rising edge, based on the values that their inputs stabilized to over the previous clock cycle; we imagine "photographing" their internal states just after the clock's rising edge. Thus, we define our semantics by a function that takes as arguments (1) the values attained during a given clock cycle on the primary input wires and (2) the internal state latched in at the beginning of that clock cycle, and returns the next "snapshots": the values on the output wires just before the end of the cycle, and the internal state immediately after the next rising edge. This function, called `DUAL-EVAL`, computes two results: outputs and next state. `DUAL-EVAL` is so-called because it uses two passes over the circuit netlist to compute these values, one pass to update the internal wire values, and another pass to update the internal state. We explain `DUAL-EVAL` in some detail below.

Now imagine applying this `DUAL-EVAL` function repeatedly, starting with a given internal state and taking a list of input vectors to be read in during each clock cycle. The result of this repeated application is a list of "snapshots," that is, a list of pairs each containing the output vector and internal state at successive rising edges of the clock, in the sense described above. This iteration of `DUAL-EVAL` is performed by the function `SIMULATE`. In conventional jargon, the `DUAL-EVAL` HDL allows Mealy machines to be specified. `SIMULATE` is the corresponding simulator, that is, the corresponding operational semantics for our HDL.

Let us turn now to the "snapshot" function `DUAL-EVAL` described above. A call to `DUAL-EVAL` takes the following form:

```
(DUAL-EVAL flag function arguments state netlist)
```

A flag value of `0` or `2` determines, respectively, whether the interpreter computes the values of the output lines or the new values of the state-holding components. Values of `flag` of `1` and `3` are used to signal recursive evaluation of occurrence lists. The other arguments are as follows when `flag` is `0` or `2`:

- `function`: the name of the module to be evaluated;
- `arguments`: the list of values of the input lines for this module evaluation;
- `state`: a list of current values of the state-holding components of the module; and
- `netlist`: the netlist in which module `function` is defined.

For example, assume that we have the following netlist `NETLIST`, representing a *full-adder* module in the HDL.

```
'((FULL-ADDER (A B C)
              (SUM CARRY)
              ((T0 (SUM1 CARRY1) HALF-ADDER (A B))
               (T1 (SUM CARRY2)  HALF-ADDER (SUM1 C))
               (T2 (CARRY)       B-OR (CARRY1 CARRY2)))
              NIL)
  (HALF-ADDER (A B)
              (SUM CARRY)
              ((G0 (SUM)   B-XOR (A B))
               (G1 (CARRY) B-AND (A B)))
              NIL))
```

Regardless of the value of STATE, the following equality holds:

```
(DUAL-EVAL 0 'FULL-ADDER (LIST T F T) STATE NETLIST) = (LIST F T)
```

That is, DUAL-EVAL here returns the list of values of the FULL-ADDER outputs SUM and CARRY, when the inputs A, B, and C take values T, F, and T, respectively. The preceding equality is independent of the value of STATE because there are no state-holding elements in NETLIST in this case.

The call

```
(DUAL-EVAL 2 'FULL-ADDER (LIST T F T) STATE NETLIST)
```

returns the list of updated values of the *state-holding components* of module FULL--ADDER on the same arguments, and in this case returns NIL since the FULL-ADDER module has no state-holding components.

The examples above have all assumed Boolean values. However, the underlying evaluation model used by DUAL-EVAL is four-valued, with logical values of T, F, (Z), and (X); (Z) is the "floating value" and (X) is "undefined." All of the primitives (and, hereditarily, all defined modules) are defined on the four logical values.

The values produced by DUAL-EVAL are computed by a recursive evaluation of a module definition and its component modules. Calls to HDL primitives are handled by the subsidiary functions DUAL-APPLY-VALUE and DUAL-APPLY-STATE, which look up the semantics of the primitive in a database (see Section 2.9) and apply that semantics to the arguments.

The syntactic constraints on the language assure that this can be done efficiently, in two passes through the occurrence list. Since all of our functions, including DUAL-EVAL, are defined within the Boyer-Moore logic, we can use the logic's interpreter to simulate them for explicit input values. We use this capability extensively to "debug" our circuit designs before investing the time to prove the correctness of our circuit designs.

The treatment of time in our interpreter model is simplistic. Each application of DUAL-EVAL simulates one (implicit) "tick" of the global clock. Restrictions on the language, such as the prohibition of combinational loops, guarantee that the

evaluation will reach a "stable state" within one clock tick. We also define the "multi-clock" function named `SIMULATE`.

Definition.

```
(simulate fn inputs state netlist)
 =
(if (nlistp inputs)
    nil
  (let ((value (dual-eval 0 fn (car inputs) state netlist))
        (new-state (dual-eval 2 fn (car inputs) state netlist)))
    (cons (list value new-state)
          (simulate fn (cdr inputs) new-state netlist))))
```

This function models the recursive application of `DUAL-EVAL` over time by returning a list of 2-element lists of the form `(LIST outputs state)`, where `outputs` and `state` are the results of calling `DUAL-EVAL` with flags `0` and `2`, respectively. The argument `INPUTS` is a *list* of input vectors, one for each clock tick. The function `SIMULATE-DUAL-EVAL-2` is similar, except that it returns a single (final) state rather than a list of output-state pairs.

In addition to the definitions of `DUAL-EVAL` and `SIMULATE`, this file also contains some rewrite rules useful for opening up the definition of `DUAL-EVAL` in particular circumstances.

See Section 14.30 for the event file "dual-eval.events".

5.2 PREDICATE-HELP

The functions in this file are used in the files "predicate-simple.events" and "predicate.events".

See Section 14.31 for the event file "predicate-help.events".

5.3 PREDICATE-SIMPLE

This file contains a recognizer for well-formed netlists. The recognizers in this file are defined to be as simple as possible, and thus return Boolean results.

The predicate `TOP-LEVEL-PREDICATE-SIMPLE` is a simpler version of the circuit predicate `TOP-LEVEL-PREDICATE` in the file "predicate.events". These predicates only return a symbol indicating what main property was violated. The circuit recognizer predicates in file "predicate.events" return more useful information, but the functions there are much more complex.

Definition.

```
(top-level-predicate-simple netlist)
 =
(if (not (netlist-syntax-simple-okp netlist))
    'netlist-syntax-simple-okp-error
  (if (not (simple-dependency-table netlist))
      'dependency-table-simple-error
    (if (not (netlist-type-check-simple-okp netlist))
        'netlist-type-check-simple-okp-error
      (if (not (netlist-state-types-simple netlist))
          'netlist-state-types-simple-error
        (if (not (netlist-loadings-and-drives-simple netlist))
            'netlist-loadings-and-drives-simple-error
          t)))))
```

The ordering of the tests in the definition of TOP-LEVEL-PREDICATE-SIMPLE is important. That is, before we check for type errors, we insist that the netlist syntax is correct. This predicate is not sufficiently general to recognize circuits with tri-state components—it does not permit a wire to be used in a bi-directional way.

We do not use these circuit predicates during our proofs; however, once we have a netlist we check its well-formedness using these predicates.

Note: we know that the two predicates TOP-LEVEL-PREDICATE-SIMPLE and TOP-LEVEL-PREDICATE (discussed in the next section) do not recognize exactly the same language. Thus we use both predicates when we test a module for well formedness, except in the case of modules that include tri-state circuits when only TOP-LEVEL-PREDICATE is used.

See Section 14.32 for the event file "predicate-simple.events".

5.4 PREDICATE

Here we define a predicate that recognizes well-formed circuits, formulated in the Hardware Description Language (HDL). The predicate TOP-LEVEL-PREDICATE has one parameter, a netlist (the normal HDL circuit description). The value of TOP-LEVEL-PREDICATE is true (T) for a well-formed netlist, but is a description of all errors detected for an ill-formed netlist. Among the errors detected are excessive fan-out, wire type mismatches, clock distribution, arity problems, duplicate names, inappropriate names, missing fields, and combinational loops. An itemized list appears below.

A second predicate LSI-TOP-LEVEL-PREDICATE has additional well-formedness checks for LSI Logic's requirements. This is important because we sometimes translate our HDL into LSI Logic's language, NDL. This predicate has three parameters:

`netlist:` a netlist, in which all names are litatoms

`token-size:` maximum allowed name length (should be 64)

`max-hierarchical-name-length:`
maximum allowed length for LSI Logic's
hierarchical names (should be 255)

First let us look at two small examples. At the end of this description we present a much larger example. Although the output of `TOP-LEVEL-PREDICATE` is intended to be self-explanatory, we annotate both input and output below with semicolons to indicate comments in the usual Lisp style.

The first example illustrates syntax errors.

```
(top-level-predicate
  '((FULL-ADDER (C A B)
                (SUM CARRY)
                ((G0 (SUM1 CARRY1) HALF-ADDER (A B))
                 (G1 (SUM CARRY2) HALF-ADDER (SUM1 C EXTRA)) ; too many inputs
                 (G2 (CARRY) B-OR (CARRY1 CARRY2)))
                NIL)
    (HALF-ADDER (A B)
                (SUM CARRY)
                ((37 (SUM) B-XOR (A B)) ; 37 is not a valid occurrence name
                 (G1 (CARRY) B-AND (A B)))
                NIL)))

 =

;; There are two syntax errors, one in each module.
 (NET-ERROR
  'NETLIST-SYNTAX-ERRORS
  (LIST
   ;; first, the extra-input error in module FULL-ADDER
   (NET-ERROR
    '(MODULE FULL-ADDER)
    (LIST
     ;; the first error is in the occurrences field of FULL-ADDER
     (NET-ERROR 'MODULE-OCCURRENCES
      (LIST
       ;; first note that occurrence G1 has the wrong number of inputs
       (NET-ERROR
        '(OCCURRENCE G1)
        (LIST
             (NET-ERROR 'OCCURRENCE-FUNCTION
                        (LIST (NET-ERROR 'WRONG-NUMBER-OF-INPUTS
                                         '(OCC-FUNCTION HALF-ADDER
                                                        (EXPECTED 2)
                                                        (GOT 3)))))))
       ;; next note that EXTRA is used but was never defined
```

```
      (NET-ERROR 'NON-DEPENDS-NOT-IN-SIGNALS
                 '(EXTRA))))))
  ;; now, for the error in module HALF-ADDER
  (NET-ERROR
   '(MODULE HALF-ADDER)
   (LIST
    ;; the error is in the occurrences field here too
    (NET-ERROR 'MODULE-OCCURRENCES
     (LIST
      ;; 37 is a bad occurrence name
      (NET-ERROR '(OCCURRENCE 37)
                 (LIST (NET-ERROR 'OCCURRENCE-NAME
                                  (NET-ERROR 'BAD-NAME 37)))))))))
```

Here is a second example. This one illustrates an error that is more "semantic" in nature.

```
(top-level-predicate
  '((FOO (A B)
         (C)
         ((G1 (D) T-BUF (A B)) ;; so, D is a tri-state wire
          (G2 (C) B-NOT (D)))  ;; so, D is a Boolean wire
         NIL)))

 =

;; The label NETLIST-ERRORS indicates a ``semantic'' error.
;; In this case, D is a tri-state output wire for the T-BUF
;; but it is a Boolean input to the B-NOT.
 (NET-ERROR
  'NETLIST-ERRORS
  (LIST
   (NET-ERROR
    '(MODULE FOO)
    (LIST
        (NET-ERROR 'IO-TYPE-CONFLICTS
                   (LIST (NET-ERROR '(SIGNAL D)
                                    '((INPUT-TYPE BOOLP)
                                      (OUTPUT-TYPE TRI-STATE))))))))))
```

Let us turn now to details about the predicates. The netlist predicates work in two stages. First, they (functions `NETLIST-SYNTAX-OK` and `LSI-NETLIST--SYNTAX-OK`) check the netlist for syntax errors. Then, they check for other errors by attempting to construct a database of netlist properties (function `NETLIST--PROPERTIES`), similar to the primitive database (see Section 2.9). This database may be viewed as an extension of the constant `(PRIMP-DATABASE)` (defined in Section 5.1) to a table for all the modules in the netlist, though the properties of interest need to be given as a parameter to `NETLIST-PROPERTIES`. That is, this function builds a table associating with each module name various properties such as drives, input names, loads, and so on.

Also included is function `NETLIST-DATABASE`, which also constructs a database of netlist properties but does not take a list of desired properties as an input. Instead, the netlist database returned by this function contains all the properties appearing in `PRIMP-DATABASE`, except for `LSI-NAME`, `NEW-STATES`, and `RESULTS` properties. `NETLIST-DATABASE` assumes there are no syntax errors in the netlist.

In addition, the following functions return single properties of a netlist, module, or primitive.

Number of gates, pads, primitives, or transistors:	`primitive-count`

Output dependencies:	`dependency-table`
	`output-dependencies`
	`out-depends`

Signal types:	`netlist-type-table` `I/O-types`
State types:	`netlist-state-types` `state-type-requirement`
Loadings and drives:	`netlist-loadings-and-drives` `loadings-and-drives`

The functions above were defined under the implicit assumption that the primitive database is well-formed, as well as the netlist we are analyzing. We check the well-formedness of the database with function `PRIMP-DATABASE-PREDICATE`, as we now describe.

5.4.1 The Primitive Database

The primitive database is checked by the function `PRIMP-DATABASE-PREDICATE` for the presence and consistency of *properties*, that is, values of the fields associated with each primitive. The primitive properties and some requirements on them are:

DELAYS. Signal delay as a function of loading. There should be an entry for each output. Each entry has the following form.

```
  ((<low to high slope> <low to high intercept>)
   (<high to low slope> <high to low intercept>))
| <input name>
| (OR <input name>*)
```

An input name means that the output has the same delay as the input. The `OR` form means that the output has the same delay as one of the named inputs.

DRIVES. Measure of the loading a signal can tolerate. There should be an entry for each output. Each entry has the following form, where the optional designator "mA" stands for milliAmps.

```
  <number>
| (<number> mA)
| <input name>
| (MIN <input name>*)
```

An input name means that the output has the same drive value as the input. The `MIN` form means that the output has the least drive value of the named inputs.

INPUT-TYPES. There should be one type for each input. Acceptable types are `boolp`, `clk`, `free`, `level`, `parametric`, `tri-state`, `ttl`, `ttl-tri-state`. Only `tri-state` is acceptable for primitive `t-wire`. Bi-directional I/O signals should be of type `tri-state` or `ttl-tri-state`.

INPUTS. List of input signal names.

LOADINGS. There should be an entry for each input. Each entry has the following form, where the optional designator "pf" stands for picoFarads.

```
<number> | (<number> pf)
```

LSI-NAME. LSI Logic's name for the primitive, possibly with reordered inputs. Reordered input signals should include all and only the signals in the `INPUTS` property.

NEW-STATES. The property, when evaluated by `DUAL-EVAL`, should give a single state value or a list of two or more state values, corresponding to the `STATES` property. Each new state value should depend only on `STATES` and `INPUTS`. If this property is present, `STATES` and `STATE-TYPES` should also be present.

OUT-DEPENDS. There should be an entry for each output. Each entry should be the subset of `INPUTS`, on which the corresponding output depends. An output may not depend on other signals if it is a constant or if it is extracted from the state, representing storage devices.

OUTPUT-TYPES. There should be one type for each output. Acceptable types are `boolp`, `clk`, `level`, `parametric`, `tri-state`, `ttl`, `ttl-tri-state`. The type given means that the output has the same type as the input. Only `tri-state` is acceptable for primitive `t-wire`. Bi-directional I/O signals should have the same type as they do in `INPUT-TYPES`, either `tri-state` or `ttl-tri-state`.

OUTPUTS. List of output signal names.

RESULTS. The property, when evaluated by `DUAL-EVAL`, should give one value for each output. Each output value should depend only on `STATES` and the `OUT-DEPENDS` entry for the output.

STATE-TYPES. The value should be a single state type or a list of two or more state types, corresponding to the `STATES` property. Acceptable state types are composed from the following; an exception is that there is a numeric (controller) component to the state of the `mem-32x32` primitive.

```
  (RAM (boolp*))
| (ROM (boolp*))
| (STUB (boolp*))
| boolp
```

If this property is present, `STATES` and `NEW-STATES` should also be present.

STATES. The value should be a single name, or a list of two or more names. A name represents a storage device. If this property is present, `NEW-STATES` and `STATE-TYPES` should also be present.

GATES. Number of gates in the primitive.

PADS. Number of pads in the primitive. This property is not required.

PRIMITIVES. Number of primitives (usually one). The value is zero for pseudo-primitives id and t-wire.

TRANSISTORS. Number of transistors in the primitive.

5.4.2 Syntax Requirements

The syntax of a netlist in the `DUAL-EVAL` HDL is given in Figure 5.1. The syntax is described mostly in an informal Backus-Naur Form (BNF). To be sure that a netlist is meets the syntactic requirements, the function `TOP-LEVEL-PREDICATE` can be used to check a concrete netlist using the Nqthm evaluator `R-LOOP`.

The notation is as follows:

Figure 5.1: HDL Syntax

```
<netlist>               ::=   ( <module>* )

<module>                ::=   ( <module name> <module inputs>
                                              <module outputs>
                                              <module occurrences>
                                              <module state names>
                                              [ <annotation> ] )

<module name>           ::=   <name>

<module inputs>         ::=   ( <name>* )

<module outputs>        ::=   ( <name>* )

<module occurrences>    ::=   ( <occurrence>+ )

<module state names>    ::=   NIL | <name> | ( <name> <name>+ )

<annotation>            ::=   ( ( <key> . <value> )* )

<occurrence>            ::=   ( <occurrence name> <occurrence outputs>
                                                  <occurrence function>
                                                  <occurrence inputs>
                                                  [ <annotation> ] )

<occurrence name>       ::=   <name>

<occurrence outputs>    ::=   ( <name>* )

<occurrence function>   ::=   <name>

<occurrence inputs>     ::=   ( <name>* )

<name>                  ::=   <simple name> | <indexed name>

<simple name>           is    a litatom.

<indexed name>          is    a shell object, constructed by
                              (index <simple name> <number>),
                              where <number> is a numberp.

<key>                   is    unrestricted.

<value>                 is    unrestricted.
```

- `<x> ::= y` means that `<x>` is a nonterminal symbol and its definition is `y`. Grammar symbols, nonterminal and terminal, are surrounded by angle brackets `<>`.
- Within the definition `y`:
  - The vertical bar | means "or" and separates alternative definitions.
  - Text in square brackets [...] is optional.
  - A * following a grammar symbol or a sequence of symbols in parentheses indicates that the symbol or sequence can appear zero or more times.
  - A + following a grammar symbol or a sequence of symbols in parentheses indicates that the symbol or sequence can appear one or more times.

Additional syntax requirements are:

- No `<module name>` is the same as a primitive name, and there are no duplicate `<module name>`s in the `<netlist>`.
- There are no duplicate signal names within a `<module>` except for I/O-signals (intersection of `<module inputs>` and `<module outputs>`). The signals of a module are its inputs and `<occurrence outputs>` from all its occurrences.
- Within a `<module>`, all `<module outputs>` are generated once and only once as `<occurrence outputs>`.
- All `<occurrence inputs>` within a `<module>` are signals of the module.
- `<module state names>` are a subset of the module's `<occurrence name>`'s.
- There are no duplicate `<occurrence name>`'s within a module.
- Every `<occurrence function>` names either a primitive or a `<module>` defined in the netlist after the `<module>` where the `<occurrence function>` appears.
- Numbers of `<occurrence inputs>` and `<occurrence outputs>` are the same as the numbers of inputs and outputs required by the definition of the module or the description of the primitive named by the `<occurrence function>`.

LSI Logic's Network Description Language (NDL) has the following additional syntax requirements:

- A `<name>` is a standard litatom beginning with an upper case letter and containing only upper case letters, digits, hyphens (-), and underscores (_). A `<name>` can contain at most 64 characters (`token-size`). No name can be an NDL keyword.

- LSI Logic uses hierarchical names to provide a unique name for each signal in a circuit. The name is composed by appending `/<occurrence name>` for each occurrence in an instance tree until a primitive is reached; at that point `/<name>` is appended, where `<name>` is the name of a signal in the occurrence that is an instance of the primitive. No hierarchical name can contain more than 255 characters (`max-hierarchical-name-length`).

- No signal name (module input or occurrence output, including module outputs) can be the same as an occurrence name except that if an occurrence has only one output, the output name can be the same as the name of that occurrence.

- No signal name or occurrence name in a module can be the same as the name of any function referenced in that module. If the function is a primitive, LSI Logic's name for it is the one that cannot be used as a signal or occurrence name.

5.4.3 Other Well-Formedness Requirements

Signal Types. Type requirements for all signals in a netlist are inferred from the types of its primitives. Contradictory type requirements give an error. I/O signals should have `tri-state` output types and either `tri-state` or free input types. All modules with `T-WIRE` type inputs should have `tri-state` input types. Otherwise, the output type of a signal is required to be a subtype of its input type.

Loadings and Drives. When a signal is generated, it has a limited strength, or drive. When the signal is used, the drive is depleted by some amount, the loading. In a well-formed netlist, the loading on any signal cannot exceed its drive. An overloaded signal gives an error. This computation provides a crude measure of acceptable fanout.

Output Dependencies. For each signal in the netlist, we compute an output dependency list. An output dependency is the name of an input on which the signal combinationally depends. Output signals do not depend on the inputs when they are constants or are derived solely from the internal state of a module.

It is an error if a signal `S` (occurrence input or module output) depends on an unknown signal. In particular, every occurrence input must be "already defined" in the sense that it either appears among the module's inputs or that it appears in a preceding occurrence's output list. The output dependency computation gives errors for circularities (combinational wiring loops or feedback) in circuit descriptions. This restriction demands that the value of every `<occurrence output>` can be computed in a single pass.

State Types. The state or list of states, appearing in a module definition, should correctly reflect the state requirement of the module. This is checked by constructing a mapping from module occurrence names to state types. For each occurrence of a submodule or primitive with state, the name of the occurrence is mapped to the state type required by the submodule or primitive. The state type of a primitive is given in the primitive database. It is an error if the states in the module definition do not include all and only the occurrence names in the mapping. It is an error if the states listed in a module definition are not the same as the states for which types are computed, ultimately from primitive state types.

Tri-State Signal Checks. A signal that is an input to a `t-wire` primitive cannot be fanned out. In addition, a signal can be an input to at most one `t-wire` primitive. Finally, no I/O signal (i.e., signal that is in both the input and output lists of the module) can be an input or an output of the primitive `ID` (which declares aliases for signal names).

See Section 14.33 for the event file "predicate.events".

5.5 PREDICATE-TESTS

This file contains many netlists with a variety of problems. We use these netlists to check that our netlist predicate, `TOP-LEVEL-PREDICATE`, recognizes these netlists as ill-formed. This file in not actually part of the FM9001 run.

See Section 14.34 for the test file "predicate.tests".

5.6 PRIMITIVES

Perhaps the most important command in this file is `(RESULT-AND-STATE-LEMMAS)`. It generates a large number of rewrite rules about the primitive (built-in) `DUAL-EVAL` hardware modules. Note that these lemmas are all generated automatically by the command above, which actually calls on several macros that are defined in the file "primitives.lisp" (Section 2.10). The few additional events in this file are mainly technical in nature, so we will not discuss them here. Instead, let us take a look at the events generated by `(RESULT-AND-STATE-LEMMAS)` for a flip-flop primitive, `FD1S`. In each case the event is preceded by a short explanatory comment.

Our convention for naming the predicate that recognizes valid subnets in a netlist is to concatenate the "`&`" character to the end of the module name. Note that every netlist is "valid" for primitives, because their definition is built into the semantics (`DUAL-EVAL`, see Section 5.1) of our hardware description language. In particular, every netlist correctly "represents" the primitive `FD1S`.

```
(DEFN FD1S& (NETLIST) T)
```

We disable the definition of each netlist recognizer.

```
(DISABLE FD1S&)
```

The minimal (sub)netlist generated for correctly defining `FD1S` is empty, since `FD1S` is a primitive.

```
(DEFN FD1S$NETLIST NIL NIL)
```

The following `$VALUE` lemma gives the semantics for the output wires of an `FD1S` primitive in terms of a simple specification function. That is, it says that the values on the two output wires of this device are (in order) the value of the state (suitably "buffered") followed by the negated value of the state.

```
(PROVE-LEMMA FD1S$VALUE (REWRITE)
    (IMPLIES (FD1S& NETLIST)
             (EQUAL (DUAL-EVAL 0 'FD1S (LIST D CP TI TE) STATE
                               NETLIST)
                    (CONS (F-BUF STATE) (CONS (F-NOT STATE) 'NIL))))
    ((ENABLE FD1S& PRIMP DUAL-APPLY-VALUE)
     (EXPAND (DUAL-EVAL 0 'FD1S (LIST D CP TI TE) STATE NETLIST))))
```

We disable all `$VALUE` lemmas.

```
(DISABLE FD1S$VALUE)
```

The following `$STATE` lemma asserts that the next internal state of the `FD1S` device is the value of the test-in input `TI` if the test-enable line `TE` is high; otherwise, it is the value of the data input `D`.

```
(PROVE-LEMMA FD1S$STATE (REWRITE)
    (IMPLIES (FD1S& NETLIST)
             (EQUAL (DUAL-EVAL 2 'FD1S (LIST D CP TI TE) STATE
                               NETLIST)
                    (F-IF TE TI D)))
    ((ENABLE FD1S& PRIMP DUAL-APPLY-STATE)
     (EXPAND (DUAL-EVAL 2 'FD1S (LIST D CP TI TE) STATE NETLIST))))
```

The `$STATE` lemmas are kept disabled.

```
(DISABLE FD1S$STATE)
```

See Section 14.35 for the event file "primitives.events".

5.7 UNBOUND

This file defines functions `UNBOUND-IN-BODY` and `ALL-UNBOUND-IN-BODY` that check that a given name or (respectively) names do not occur as an output of any occurrence in a given "body" (occurrence list). The final two lemmas in the file formalize the idea that if a name is not an output of an occurrence list, then it is not bound by the evaluation of the module using `DUAL-EVAL`.

When reasoning by induction about recursive module generators, it is often necessary to know that one or more signal names in the body (occurrence list) being generated do not appear as outputs, as bound by `DUAL-EVAL`. This knowledge, together with the lemmas referred to above, allows us to deduce that the values of those signal names in a binding list produced by running `DUAL-EVAL` is the same as their values in the input binding list.

See Section 14.36 for the event file "unbound.events".

5.8 VECTOR-MODULE

This file defines an induction scheme for later use in proofs about certain "vector modules," along with vector versions of the primitives `B-BUF`, `B-OR`, `B-XOR`, `PULLUP`, and `T-WIRE`. These are all defined using the macro `VECTOR-MODULE`; see Section 2.8 for an example of what this really does.

See Section 14.37 for the event file "vector-module.events".

5.9 TRANSLATE

The function `LISP-NETLIST` converts an Nqthm netlist constant, which may include `INDEX` shells, to an Nqthm constant that does not contain such shell objects. The following example is obtained by mere evaluation, using the Nqthm logic "read-eval-print" loop, `R-LOOP`:

```
(lisp-netlist
 (list (index 'v-buf 2)
       (list (index 'a 0) (index 'a 1))
       (list (index 'y 0) (index 'y 1))
       (list (list (index 'g 0)
                   (list (index 'y 0))
                   'b-buf
                   (list (index 'a 0)))
             (list (index 'g 1)
                   (list (index 'y 1))
                   'b-buf
                   (list (index 'a 1))))
```

```
        nil))

  =

 '(V-BUF_2 (A_0 A_1)
           (Y_0 Y_1)
           ((G_0 (Y_0) B-BUF (A_0))
            (G_1 (Y_1) B-BUF (A_1)))
           NIL)
```

Finally, we discuss the function `COLLECT-PRIMITIVES`. Given a module name and a netlist that defines a module with that name, one can imagine the following graph. Its nodes are labeled with module names and its root is the given module name. The list of children of any node is simply the list of all module names referenced in the given module's occurrence list. Notice that the tips of this graph are all primitives, at least for any well-formed netlist. The function `COLLECT-PRIMITIVES` takes as inputs a module name and a netlist, and returns the list of all primitive module names that are leaves of the graph described above.

See Section 14.38 for the event file "translate.events".

Chapter 6

TWO SIMPLE EXAMPLES

The following two sections are not used elsewhere. Rather, they provide simple examples of the use of our HDL.

6.1 EXAMPLES

In this file we show how to verify two simple combinational modules, which can be used to build an adder. Also we develop a one-bit tri-state data bus, including specification and proof of correctness.

See Section 14.39 for the event file "examples.events".

6.2 EXAMPLE-V-ADD

This file contains an exercise in developing an n-bit ripple-carry adder, including specification and proof of correctness, from `HALF-ADDER` and `FULL-ADDER` modules defined in the previous file.

See Section 14.40 for the event file "example-v-add.events".

Chapter 7

MISCELLANEOUS COMBINATIONAL HARDWARE MODULES AND N-BIT REGISTERS

This chapter describes a number of miscellaneous hardware modules. We develop the theory for the propagate-generate ALU and describe how we generate simple registers.

7.1 PG-THEORY

These events develop a propagate-generate specification function `TV-ADDER` that is later implemented with hardware modules. We prove that `TV-ADDER` is equal to a ripple-carry adder `V-SUM`. Ripple-carry adder implementations take time linear in the size of their inputs, but a propagate-generate adder takes logarithmic time.

Here is a crash course on the basic algorithm for those not so familiar with adder design. The idea of a propagate-generate adder is to separate out the following two notions, *propagate* and *generate*. The *generate* from the addition of two bit vectors is `T` if and only if the addition of the two bit vectors produces an output carry regardless of the input carry value. The *propagate* bit is similar, except that when this bit is set, we only know that there will be a carry out under the assumption that the carry in is set. An important observation is that the propagate and generate may be produced in logarithmic time by a divide-and-conquer algorithm. Since the carry out may be computed rapidly (in constant time) from the propagate and generate and the carry in, it is not hard to see that the sum operation may be carried out in log time.

The function `TV-ADDER` is crucial here. Its definition assumes that the `TREE--SIZE` of the `TREE` argument is expected to be equal to the length of both inputs `A` and `B`. It returns a list whose first two bits are respectively the propagate and generate from the addition of `A` and `B`, and whose remaining elements are the sum.

See Section 14.41 for the event file "pg-theory.events".

7.2 TV-IF

This file defines a parameterized family of multiplexors whose control value is buffered when necessary as it is fanned out, using a tree to specify the shape of the control fan-out. The specification function for this multiplexor (family) is the four-valued vector "if" from "f-functions" (see also Section 4.10). The final theorem in this file states the correctness of these multiplexors.

Theorem. `TV-IF$VALUE`

```
(implies
 (and (tv-if& netlist tree)
      (properp a) (properp b)
      (equal (length a) (tree-size tree))
      (equal (length b) (tree-size tree)))
 (equal (dual-eval 0
                   (index 'tv-if (tree-number tree))
                   (cons c (append a b))
                   state
                   netlist)
        (fv-if c a b)))
```

Note that we do not use our vector macros in this file, because they were not developed for these tree-based module generators.

See Section 14.42 for the event file "tv-if.events".

7.3 T-OR-NOR

The goal of the following events is to define a fast zero detector. A simple zero detector may be built simply by OR-ing together all bits of a bit vector and then negating the result. However, we want to use negated logic where possible, for performance reasons: NOR gates are typically faster than OR gates. Moreover, we want the propagation delay to be proportional to the log of the length of the input vector, and hence we wish to use a tree-based algorithm such as is used in the preceding section, Section 7.2.

At the top level, then, we may view the fast zero detector as a multi-input NOR module. Our requirements for building such a module are that it be built

out of negated logic (NAND and NOR gates) as well as that it have logarithmic propagation delay. In order to satisfy these requirements, we use an algorithm that generates either OR or NOR modules, according to a parity argument. When we finally use this algorithm to build a fast zero detector, we choose an appropriate parity based on the height of the tree of gates.

Here are two samples of the fast zero detector, for eight bits and for three bits respectively. Recall from Section 5.9 that the function `LISP-NETLIST` removes calls of the shell constructor `INDEX` in favor of underscore characters.

```
(lisp-netlist (tv-zerop$netlist (make-tree 8)))

=

'((TV-ZEROP_8 (IN_0 IN_1 IN_2 IN_3 IN_4 IN_5 IN_6 IN_7)
              (OUT)
              ((GO (OUT) T-NOR_8 (IN_0 IN_1 IN_2 IN_3 IN_4 IN_5 IN_6 IN_7)))
              NIL)
  (T-NOR_8 (A_0 A_1 A_2 A_3 A_4 A_5 A_6 A_7)
           (OUT)
           ((LEFT (LEFT-OUT) T-OR_4 (A_0 A_1 A_2 A_3))
            (RIGHT (RIGHT-OUT) T-OR_4 (A_4 A_5 A_6 A_7))
            (OUTPUT (OUT) B-NOR (LEFT-OUT RIGHT-OUT)))
           NIL)
  (T-OR_4 (A_0 A_1 A_2 A_3)
          (OUT)
          ((LEFT (LEFT-OUT) T-NOR_2 (A_0 A_1))

           NIL)
  (T-NOR_2 (A_0 A_1)
           (OUT)
           ((LEAF (OUT) B-NOR (A_0 A_1)))
           NIL)
  (B-BUF (IN)
         (OUT)
         ((G0 (OUT- OUT) B-NBUF (IN)))
         NIL))
```

See Section 14.43 for the event file "t-or-nor.events".

7.4 FAST-ZERO

Although the propagate-generate adder described in Section 7.1 provides its outputs quickly (in time logarithmic in the input width), nevertheless some of those outputs have greater delay than others. For instance, the least significant bit of the sum is produced very rapidly, while the most significant bit takes longer. One of the critical paths in the ALU, of which the present zero-detector is a part, is a path containing the most significant bit output from the ALU. Therefore, we bias the operation of the zero-detector so that the delays from the two most significant input bits are minimized. Interestingly, further analysis using LSI Logic's timing analysis tool showed that no gain was realized using this approach, because the tree of gates in the zero detector gained an additional gate delay on the third most significant output bit.

See Section 14.44 for the event file "fast-zero.events".

7.5 V-EQUAL

Our word-equality tester simply lays down XOR gates for bitwise comparison, and then uses the zero detector from Section 7.3 to finish the test.

See Section 14.45 for the event file "v-equal.events".

7.6 V-INC4

This file contains a 4-bit incrementer with parallel carry look-ahead.

See Section 14.46 for the event file "v-inc4.events".

7.7 TV-DEC-PASS

The decrement-pass unit is used in register-indirect modes to compute the effective address quickly. There are two possibilities for the effective memory address, depending on whether or not the pre-decrement mode is set. The decrement-pass unit either decrements the address given to it or else just passes it through. We implement this unit using a propagate-generate based decrementer. Using the carry input as a control line, we either subtract `1` or `0`.

The combination of the following two lemmas shows that the decrement-pass unit has the desired semantics.

Theorem. `DEC-PASS$VALUE`

```
(implies
 (and (dec-pass& netlist n)
      (not (zerop n))
      (equal (length a) n)
      (properp a))
 (equal (dual-eval 0 #i(dec-pass n) (cons c a) state netlist)
        (f$dec-pass c a)))
```

Theorem. `F$DEC-PASS=DEC-OR-PASS`

```
(implies
 (and (bvp v)
      (boolp dec)
      (not (equal (length v) 0)))
 (equal (f$dec-pass dec v) (if* dec (v-dec v) v)))
```

See Section 14.47 for the event file "tv-dec-pass.events".

7.8 REG

This file defines two families of scanned registers, one write-enabled and one not. For those unfamiliar with this terminology, a scanned register is one that operates "normally" as a simple n-bit register, but can also operate as a *shift register*. A shift register is a sequence of one-bit registers where at each clock tick, the so-called *scan input* is latched into the first one-bit register and each bit of state is moved into the next bit of state. A *write-enabled* scan register is one that has an extra `write-enable` input that must be on in order for new values to be stored in the state.

An example evaluation of our scanned-register generators is shown below. The `DEL4` primitive is a 4-nanosecond delay buffer. We add this to ensure that there is sufficient hysteresis in the system, i.e., to ensure that minor variances in propagation of the clock signal to some state-holding devices do not cause premature changes to the inputs of other state-holding devices. Also, buffers are added to deal with fan-out on the write-enable and test-enable inputs. When the load demands are sufficiently great, `B-BUF-PWR` buffers are used in place of the `B-BUF` buffers shown below.

```
(lisp-netlist (reg* 3))

 =

'(REG_3 (CLK TE TI D_0 D_1 D_2)
        (Q_0 Q_1 Q_2)
        ((TE-BUFFER (TE-BUF) B-BUF (TE))
         (TI-DEL (TI-BUF) DEL4 (TI))

See Section 14.48 for the event file "reg.events".

Chapter 8

SPECIFICATION AND IMPLEMENTATION OF THE ALU

The first section below provides a user-level specification of the ALU at the bit level. Specifications at the natural number and integer level may be found in Section 13.2. The remaining sections of this chapter develop the implementation of our ALU.

8.1 ALU-SPECS

This file contains the high-level specification of the ALU, `V-ALU`. This function returns a carry bit, an overflow bit, a zero bit, and a bit vector of which the top bit is the negative bit. This ALU performs 14 different operations, including add-with-carry, add, shifting operations, and so on.

`V-ALU` is the bit-vector specification of the ALU. There are two other specification functions for the ALU, to be found in the file "alu-interpretation.events" (see Section 13.2). One function is `V-ALU-NAT`, which describes the ALU from the perspective of natural number operations. The other is the analogous function for (twos complement) integers, `V-ALU-INT`.

There are a number of simple rewrite rules in this file that we find useful. For example, since the ALU is used for the pre-decrement and post-increment operations on addresses, the following rewrite rule is used to remove calls of the ALU specification in favor of incrementing and decrementing operations.

Lemma. `BV-V-ALU-ALU-INC-ALU-DEC`
```
(and
```

```
(equal (bv (v-alu c a b (alu-inc-op)))
       (v-inc a))
(equal (bv (v-alu c a b (alu-dec-op)))
       (v-dec a)))
```

See Section 14.49 for the event file "alu-specs.events".

8.2 PRE-ALU

The ALU is essentially a tree with 32 cells at the leaves. Each of these cells performs the operation called for by the op-code. In fact, the cells have inputs that are controlled by so-called mode, propagate, and generate inputs, all of which are derived from the op-code together with two other control inputs, the zero input and the swap input.

This file defines the decoding logic necessary to generate the aforementioned mode, propagate, and generate inputs for the ALU cells. The functions `DECODE-GEN`, `DECODE-PROP`, and `DECODE-MODE` use random logic that has been designed to implement the table in this event file, as discussed in the next section, 8.3. It is interesting to note that these modules are defined by specifying their logic and using the `DEFN-TO-MODULE` macro (see Section 2.6) to generate the HDL descriptions automatically from these specifications. Here we also define a function `CARRY-IN-HELP` that provides the carry input for the entire ALU.

Further explanations of the ALU implementation may be found in the next section.

See Section 14.50 for the event file "pre-alu.events".

8.3 TV-ALU-HELP

Let us now provide a more high-level view of the definition of the ALU. The complete ALU is composed of a number of modules: `CARRY-OUT-HELP`, `TV-ALU-HELP`, `T-CARRY`, `SHIFT-OR-BUF`, `OVERFLOW-HELP`, and `V-ZEROP`. There are also certain parts of the ALU that are not included in the `CORE-ALU*` module because their computation is pipelined. These are the modules `CARRY-IN-HELP`, `DECODE-MODE`, `DECODE-PROP`, and `DECODE-GEN` discussed in the preceding section.

The heart of the ALU is the module `TV-ALU-HELP`, which is a propagate-generate ALU built in the style of a propagate-generate adder such as the specification `TV-ADDER` described in Section 7.1. However, instead of a 3-way exclusive OR to compute the sum at the leaves, we define `ALU-CELL` to do the appropriate computation at the leaves depending on the op-code. Note that since this module generator is tree-based, we do not have any macros to generate the HDL description automatically; hence the function `TV-ALU-HELP*` is hand-coded.

In order to make sense of this `ALU-CELL` module, let us consider the following portion of a table taken from a comment in the preceding section's event file. The

"mode" bit indicates whether or not the carry-in is to be used.

```
FM9001   Mode  Prop  Gen C-in  C-out  Ovfl  Comment
opcode         aab   aab
3210            n     nn

0011     t     tft   ftt   f   co     *     Add

1011     f     tff   fft   x   f      f     XOR
```

Let us start with the second of the two rows displayed here. The XOR instruction has op-code `1011`, and since XOR is *not* an arithmetic operation (add, subtract, increment, or decrement), the mode flag is set to `f`. The basic operation of the `ALU-CELL` is the `B-EQUV3` primitive applied to the propagate, generate, and mode bits. These propagate and generate bits are produced respectively by the `P-CELL` and `G-CELL` modules defined below.

The basic motivation for our approach is that we need to produce propagate and generate bits for the arithmetic operations, and fortuitously we can compute the output from these two bits and the mode/carry bit, uniformly for all arithmetic op-codes, by using the `B-EQUV3` primitive. For the non-arithmetic op-codes these propagate and generate bits are computed so that the `B-EQUV3` gate gives the correct answer. Let us turn now to how these bits are computed.

Continuing with the XOR row displayed above, we note that the propagate bit is simply equal to the `a` input, since that is the only one marked with a `t`. However, for the Add operation described on the first row, the propagate bit is the logical OR of the `a` and `b` bits. More generally, the propagate bit is the logical OR of those of the `a`, negated `a`, and `b` bits that are marked with a `t` in the table above. This fact is illustrated by the following theorem, which the prover can easily check.

```
(equal
 (p-cell a an b pa pan pb)
 (or (and a pa)
     (and an pan)
     (and b pb)))
```

Actually, `P-CELL` is implemented using NAND gates, for efficiency reasons.

The generate bit is obtained similarly, but negated logic is used.

```
(equal (g-cell a an bn ga gan gbn)
       (not (or (and a ga)
```

```
                (and an gan)
                (and bn gbn))))
```

The generate field from the XOR line in the table above is `fft`, where the `t` bit is the `bn` (negated `b`) value, and hence the value returned by `G-CELL` is simply `b`. For the `Add` line, the generate field is `ftt`, so the result is the AND of `a` and `b`.

Finally let us turn to `ALU-CELL`. Its arguments are a carry input `c` resulting from the propagate-generate carry look-ahead tree; inputs `a` and `b` which are two corresponding bits from the input bit vectors; and a list `mpg` that contains the mode bit, the three `Prop` bits, and the three `Gen` bits from the table that we have been discussing.

Definition.

```
(alu-cell c a b mpg)
=
;; a and b are the inputs, which are single bits from two
;; input bit vectors for the ALU.  The carry bit c is either
;; generated by  CARRY-IN-HELP from the external input carry,
;; but only for the least significant bit of the ALU, or else
;; is generated by the propagate-generate carry look-ahead logic.
(let (;; First come the bits from the 'Gen' column, right to left,
      ;; which are produced from the op-code by  DECODE-GEN.
      (gbn (car mpg))
      (gan (cadr mpg))
      (ga  (caddr mpg))
      ;; Then come the bits from the 'Prop' column, right to left,
      ;; which are produced from the op-code by  DECODE-PROP.
      (pb  (cadddr mpg))
      (pan (caddddr mpg))
      (pa  (cadddddr mpg))
      ;; Finally comes the mode bit from the table,
      ;; which is produced from the op-code by  DECODE-MODE.
      ;; Essentially, m is true if and only if we are doing
      ;; an add, subtract, increment, or decrement operation.
      (m   (caddddddr mpg)))
  (let ((an (b-not a))
        (bn (b-not b)))
    (let ((p (p-cell a an b pa pan pb))
          (g (g-cell a an bn ga gan gbn))
          (mc (b-nand c m)))
      (list p g (b-equv3 mc p g)))))
```

The call of `B-EQUV3` in the definition above can be simplified depending on the mode flag, `m`, as the following theorems demonstrate. Note that perhaps contrary to its name, `B-EQUV3` has the property that `(B-EQUV3 X Y Z)` is equal to `(NOT (B-EQUV X (B-EQUV Y Z)))`.

```
;; XOR case
(equal (b-equv3 (b-nand c f) a (not (not b)))
       (xor a b))

;; Add case
(equal (b-equv3 (b-nand c t) (or a b) (and a b))
       (b-xor3 c a b))
```

See Section 14.51 for the event file "tv-alu-help.events".

8.4 POST-ALU

This file implements part of the ALU's functionality. The modules `CARRY-OUT--HELP`, `OVERFLOW-HELP`, and `TV-SHIFT-OR-BUF` are connected to the output of the module `TV-ALU-HELP`. The module `TV-SHIFT-OR-BUF` performs right shift operations if necessary; otherwise, it just buffers its input.

`CARRY-OUT-HELP` produces the carry output of the complete ALU. For instance, if the zero input is set then the carry output is `F` regardless of anything else. For another example, the right shift instructions, the carry output is the least significant bit of the `a` input. Actually, random logic implements this module in conformance with the table at the top of the events file for Section 8.2, using the `DEFN-TO-MODULE` macro (cf. Section 2.6). The definition of `OVERFLOW-HELP` is analogous to that of `CARRY-OUT-HELP`.

See Section 14.52 for the event file "post-alu.events".

8.5 CORE-ALU

This file contains the proof that the ALU's top-level specification is implemented in two steps. First, `CARRY-IN-HELP` and `MPG` do the appropriate preprocessing (as indicated by the bindings in the `LET` form below); then, `CORE-ALU` correctly computes the ALU result. The following lemma summarizes this two-step process. It may be viewed as a composition of several lemmas that appear in this and preceding files, especially the "`$VALUE`" lemmas for `CORE-ALU`, `CARRY-IN-HELP`, and `MPG` as well as the lemma `CORE-ALU-IS-V-ALU` that relates a structural description `CORE-ALU` of the ALU with a high-level specification `V-ALU` of the ALU.

Theorem. `CORE-ALU-TOP`

```
(let ((c (car (dual-eval 0
                         'carry-in-help
                         (cons carry-in (cons f op))
                         state
                         netlist)))
      (mpg (dual-eval 0 'mpg (cons zero (cons f op))
                      state netlist)))
  (implies
   (and (core-alu& netlist tree)
        (carry-in-help& netlist)
        (mpg& netlist)
        (equal (length a) (tree-size tree))
        (bv2p a b)
        (geq (length a) 3)
        (not zero)
        (bvp op)
        (boolp carry-in)
        (equal (length op) 4))
   (equal (dual-eval
           0
           (index 'core-alu (tree-number tree))
           (cons c (append a (append b (cons zero
                                             (append mpg op)))))
           state
           netlist)
          (v-alu carry-in a b op))))
```

Another lemma in the file, `CORE-ALU-WORKS-FOR-ZERO-CASE`, describes what happens when the zero input is set. This completes our introduction to this file, except to note for those who are interested in theorem-proving details that the lemma `CASES-ON-A-4-BIT-BVP` is used as a sneaky case-splitting hint.

See Section 14.53 for the event file "core-alu.events".

Chapter 9

SPECIFICATION OF THE FM9001

The following section provides the specification of the FM9001 at the user level. The other section in this chapter is merely a presentation of a simple assembler used for testing the specification.

9.1 FM9001-SPEC

The FM9001 interpreter is defined in the standard manner: as a recursive function that repeatedly "applies" a "single-step" function.

Definition.

```
(FM9001 state n)
 =
(if (zerop n)
    state
  (FM9001 (FM9001-step state (nat-to-v 15 (reg-size)))
          (sub1 n)))
```

The definition of the "single-stepper" `FM9001-STEP` makes use of a sequence of auxiliary functions. The particular fields of an instruction word do not concern us at this point; they will be addressed once we complete our top-down high-level view of the stepper.

The `STATE` parameter to `FM9001-STEP` will be examined further below, and `PC-REG` may be thought of as the list `(LIST T T T T)` representing register 15. Let us describe the high-level structure of this "calling tree" before looking at each such function in some detail.

```
(FM9001-step state pc-reg)
-->
(FM9001-fetch  register-file-0 flags memory pc-reg)
-->
(FM9001-operand-a  register-file-1 flags memory instruction)
-->
(FM9001-operand-b  register-file-2 flags memory instruction operand-a)
-->
(FM9001-alu-operation  register-file-3 flags memory instruction operand-a
    operand-b b-address)
=
(list (list  new-register-file new-flags)  new-memory)
```

The definition of `FM9001-STEP` gives a clue to the structure of the `STATE` parameter of the interpreter function shown above. Namely: the state is of the form `(LIST P-STATE MEM)`, where `P-STATE` contains fields for the register file and the flags, and `MEM` is the processor memory. The register file, flags, and memory, together with the index of the program counter register (typically 15) expressed as a bit vector, are then handed off to the function `FM9001-FETCH`, which implements the fetch-execute cycle.

Definition.

```
(FM9001-step state pc-reg)
 =
(let ((p-state (car state))
      (mem     (cadr state)))
  (FM9001-fetch (regs p-state) (flags p-state) mem pc-reg))
```

The function `FM9001-FETCH` implements the fetch-execute cycle by obtaining the program counter `PC`, the current instruction `INS`, and the new register file obtained by incrementing the program counter, and then calling the function `FM9001-OPERAND-A` that we describe next.

Definition.

```
(FM9001-FETCH regs flags mem pc-reg)
 =
(let ((pc (read-mem pc-reg regs)))
  (let ((ins (read-mem pc mem)))
    (let ((pc+1 (v-inc pc)))
      (let ((new-regs (write-mem pc-reg regs pc+1)))
        (FM9001-operand-a new-regs flags mem ins)))))
```

The function `FM9001-OPERAND-A` obtains the first operand, `OPERAND-A`, either as an immediate value directly from the instruction word, as a value directly from register A, or else by reading from the memory using the address stored in register A (possibly pre-decremented). `OPERAND-A` is an argument of the call to the next function `FM9001-OPERAND-B`, which is given a new register file if the mode calls for pre-decrementing or post-incrementing of the first operand register.

Definition.

```
(fm9001-operand-a regs flags mem ins)
 =
(let ((a-immediate-p (a-immediate-p ins))
      (a-immediate   (sign-extend (a-immediate ins) 32))
      (mode-a        (mode-a ins))
      (rn-a          (rn-a  ins)))
  (let ((reg (read-mem rn-a regs)))
    (let ((reg- (v-dec reg))
          (reg+ (v-inc reg)))
      (let ((operand-a (if a-immediate-p
                           a-immediate
                         (if (reg-direct-p mode-a)
                             reg
                           (if (pre-dec-p mode-a)
                               (read-mem reg- mem)
                             (read-mem reg mem))))))
        (let ((new-regs (if a-immediate-p
                            regs
                          (if (pre-dec-p mode-a)
                              (write-mem rn-a regs reg-)
                            (if (post-inc-p mode-a)
                                (write-mem rn-a regs reg+)
                              regs)))))

          (FM9001-operand-b new-regs flags mem ins operand-a))))))
```

The function `FM9001-OPERAND-B` is defined analogously to the function above except that there is no immediate operand mode. Thus, the second operand, `OPERAND-B`, is obtained and passed to the next function, `FM9001-ALU-OPERATION`, along with a register file, in which the second operand register has been (possibly) updated. The value stored in the second operand register is saved (after pre-decrementing if appropriate) and passed to the ALU as the additional argument `B-ADDRESS`.

Definition.

```
(fm9001-operand-b regs flags mem ins operand-a)
 =
(let ((mode-b (mode-b ins))
      (rn-b   (rn-b  ins)))
  (let ((reg (read-mem rn-b regs)))
    (let ((reg- (v-dec reg))
          (reg+ (v-inc reg)))
      (let ((b-address (if (pre-dec-p mode-b)
                           reg-
                          reg)))
        (let ((operand-b (if (reg-direct-p mode-b)
                             reg
                            (read-mem b-address mem)))
              (new-regs (if (pre-dec-p mode-b)
                            (write-mem rn-b regs reg-)
                          (if (post-inc-p mode-b)
                              (write-mem rn-b regs reg+)
                            regs))))

          (FM9001-alu-operation
           new-regs flags mem ins
           operand-a operand-b b-address))))))
```

Finally, the function `FM9001-ALU-OPERATION` is called to return the new state, i.e., the new register file, the new flags, and the new memory. The new register file `NEW-REGS` is obtained by writing the bit vector returned by the ALU into register B, assuming that the flags are set appropriately for the given instruction (as indicated by `STOREP`) and that the mode for register B is "direct." The new flags `NEW-FLAGS` are set using the flags returned by the ALU, but only for the flags that the instruction requires to be updated. Finally, the new memory is obtained by writing the ALU's bit-vector result to the memory at the appropriate location obtained from register B, assuming that (once again) `STOREP` is set, and assuming that the mode for register B is register-indirect.

Definition.

```
(fm9001-alu-operation regs flags mem ins
                      operand-a operand-b b-address)
 =
(let ((op-code   (op-code ins))
      (store-cc  (store-cc ins))
      (set-flags (set-flags ins))
      (mode-b    (mode-b   ins))
      (rn-b      (rn-b    ins)))
  (let ((cvzbv  (v-alu (c-flag flags) operand-a operand-b op-code))
```

```
      (storep (store-resultp store-cc flags)))
  (let ((bv (bv cvzbv)))
    (let ((new-regs   (if (and storep (reg-direct-p mode-b))
                          (write-mem rn-b regs bv)
                        regs))
          (new-flags  (update-flags flags set-flags cvzbv))
          (new-mem    (if (and storep (not (reg-direct-p mode-b)))
                          (write-mem b-address mem bv)
                        mem)))

      (list (list new-regs new-flags) new-mem)))))
```

There are two more interpreter functions defined in this file. The function `FM9001-INTERPRETER` takes the program counter register as an argument. The function `FM9001-INTR` goes even further by allowing an oracle to supply the program counter for each instruction. The file concludes with some simple lemmas.

See Section 14.54 for the event file "fm9001-spec.events".

9.2 ASM-FM9001

This file contains a quick-and-dirty assembler, together with example programs at the end of the file. It produces a list that is readily converted into a memory for the behavioral specification function `FM9001`.

This assembler is not used in the proof, and nothing is proved about it. It is simply a convenient tool for testing the FM9001 specification.

See Section 14.55 for the event file "asm-fm9001.events".

Chapter 10

FM9001 HARDWARE MODULES

In this chapter we implement the bulk of the logic for the FM9001 other than the ALU.

10.1 STORE-RESULTP

This file defines hardware implementing the specification function `STORE-RESULTP`, introduced in Section 9.1, that determines when to store the answer produced by the ALU. More precisely, the ALU always produces a bit vector and some flags; this hardware decides only whether or not the bit-vector result should be stored.

See Section 14.56 for the event file "store-resultp.events".

10.2 CONTROL-MODULES

The file "control-modules.events" defines several hardware functions: a unary operation-code recognizer, a register-mode recognizer, opcode selection logic, fanout modules, decoders and encoders. These are defined in a similar manner to many previously defined modules. These are submodules of the main control logic defined in the next section.

See Section 14.57 for the event file "control-modules-events.events".

10.3 CONTROL

In this section we describe the control logic, which is perhaps the most complicated part of the FM9001 definition and proof. Most of the control logic is generated automatically, and so are most of the proof events. This section depends heavily

on macros defined in the corresponding Lisp file "control.lisp", which is mentioned in Section 2.11 but which we document here.

The goal of this file is to define the module NEXT-CNTL-STATE, which takes a 5-bit major control state (as defined below) and some other inputs and returns a 40-bit control vector. That control vector contains 5 bits comprising the "next major control state" together with 35 additional control fields. The 40-bit control vector produced by the module NEXT-CNTL-STATE controls the entire FM9001 microarchitecture and the memory protocol interface. That is, this function is literally the control logic for the FM9001. The microarchitecture of the FM9001 is shown in Figure 10.1. In this conventional engineering diagram, we see in the upper half a description of the "data path" and in the lower half a descirption of the "control logic." Obviously, this diagram is an abstraction because as drawn the control logic is not even "connected" to the data path. The 40-bit vector contained in the CNTL-STATE register literally controls the machine. The "function" NEXT-CNTL-STATE produces a new 40-bit control vector for each clock cycle, as a function of the previous values of these seven quantities: CNTL-STATE, FLAGS, RESET-, HOLD-, DTACK-, PC-REG, and the instruction register I-REG. The upper half of Figure 10.1 illustrates the principal data paths. The upper righthand corner shows the bi-directional external memory databus, and just below it is the external address bus. The REGISTER-FILE, A-REG, B-REG, I-REG, DATA-OUT, and ADDR-OUT are state-holding registers. The other blocks, e.g., the ALU are combinational logic.

An instruction is executed by the microarchitecture by reading an instruction from the DATA-BUS (which is connected to the external memory) and storing it into I-REG. The instruction is then decoded and operands are fetched and then stored into A-REG and B-REG, as necessary. This decoding and storing of operands may require several clock cycles. The result of the ALU computation is stored as specified by the instruction.

The NEXT-CNTL-STATE module is defined in the file "control.events" through the definition of several major subpieces: CONTROL-LET, DECODE-5 (defined in "control-modules.events"), NEXT-STATE, and CV. A diagram of the NEXT-CNTL-STATE module is shown in Figure 10.2. We will return to this module at the end of this section, after we present the major subpieces.

Before we are able to define the various modules that comprise NEXT-CNTL-STATE we define a set of tables and functions that specify what the NEXT-CNTL-STATE module is to do. The complicated part of this file begins with the part labeled in the event file as "Macro Execution," which contains the following three macro calls.

```
(define-control-states)

(define-control-state-accessors)
```

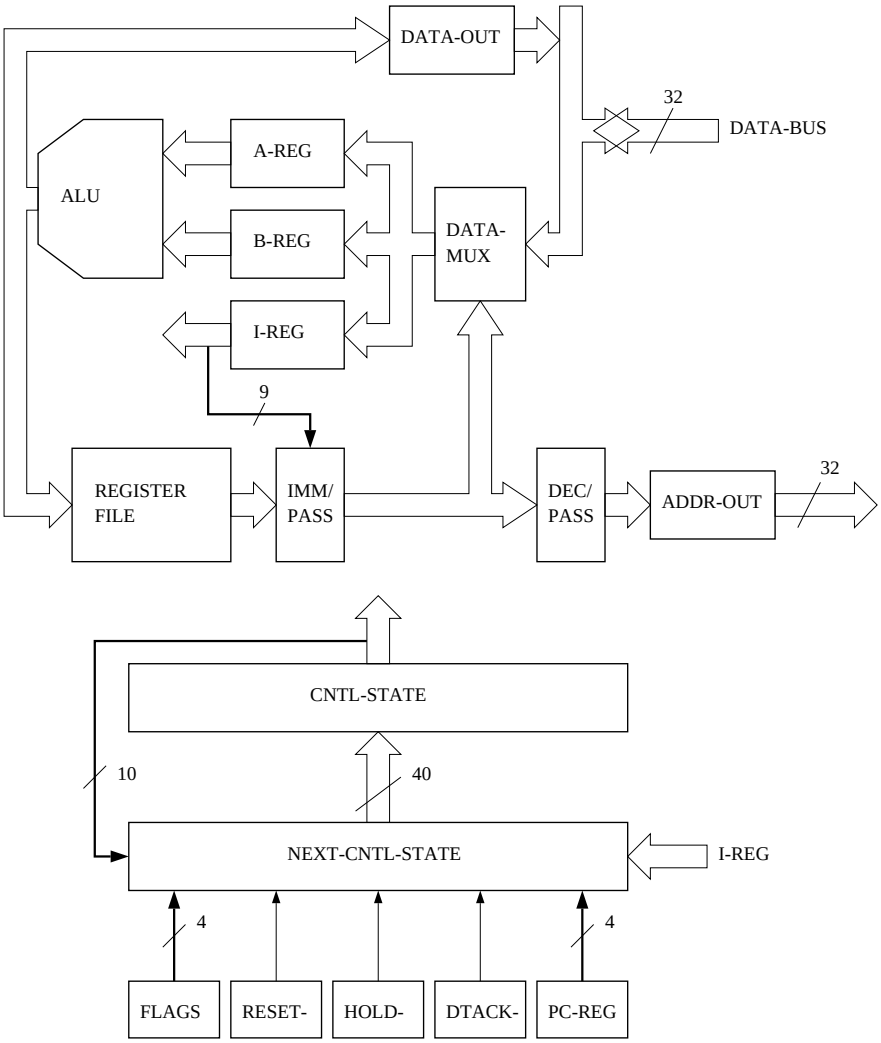

Figure 10.1: Block Diagram of the FM9001

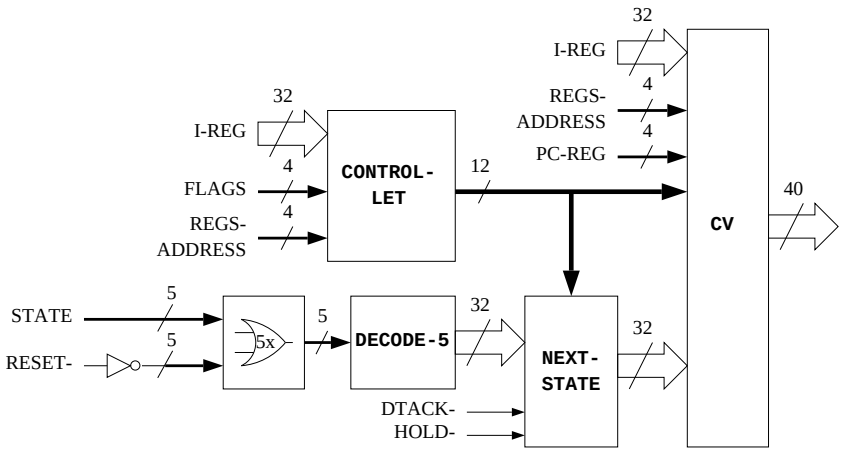

Figure 10.2: Diagram of the `NEXT-CNTL-STATE` Module

```
(define-control-vector-functions)
```

These macros, which are defined in the file "control.lisp", generate events for the control logic using a sort of microcode-style description of the control logic. Let us look at this process in more detail.

The operation of the `FM9001` is controlled by a 40-bit *control vector*. Most of the bits of this control vector directly control internal latches and selectors, the ALU, the register file, and the memory interface. For instance, one bit is a write-enable control bit for the address output latch. Especially noteworthy is a five-bit subpart of the control vector that defines the *major control state* for the machine. These 32 major control states (actually 29, since three are "unused") are used to define a finite-state machine, whose transitions depend not only on the current state but also on other inputs, including the instruction register, the data acknowledgement input, and the hold input.

The Lisp constant `*CONTROL-STATES*` defined in "control.lisp" gives symbolic names to the 32 major control states.

```
(defconstant
  *control-states*
  '((fetch0  . #v00000)  ;; setting up for instruction fetch
    (fetch1  . #v00001)  ;; checking for hold
    (fetch2  . #v00010)  ;; increment pc
    (fetch3  . #v00011)  ;; wait for data ack., read instruction

    (decode  . #v00100)  ;; decode the instruction
    (rega    . #v00101)  ;; fetch operand A from register file
    (regb    . #v00110)  ;; fetch operand B from register file
```

```
(update  . #v00111)  ;; update register file with answer

(reada0  . #v01000)  ;; setting up for operand A memory read
(reada1  . #v01001)  ;; do pre-decrement or post-increment, if necessary
(reada2  . #v01010)  ;; store the result of pre-decrement or post-increment
(reada3  . #v01011)  ;; wait for data ack., read operand A data

(readb0  . #v01100)  ;; setting up for operand B memory read
(readb1  . #v01101)  ;; do pre-decrement or post-increment, if necessary
(readb2  . #v01110)  ;; store the result of pre-decrement or post-increment
(readb3  . #v01111)  ;; wait for data ack., read operand B data

(write0  . #v10000)  ;; setting up for the instruction result write
(write1  . #v10001)  ;; may do pre-dec or post-inc, if skipped above
(write2  . #v10010)  ;; turn memory strobe on
(write3  . #v10011)  ;; wait for data acknowledgement

(sefa0   . #v10100)  ;; get register A from register file
(sefa1   . #v10101)  ;; side effect operand A register, if necessary
(sefb0   . #v10110)  ;; get register B from register file
(sefb1   . #v10111)  ;; side effect operand B register, if necessary

(hold0   . #v11000)  ;; hold state
(hold1   . #v11001)  ;; exiting hold state
(v11010  . #v11010)  ;; unused state
(v11011  . #v11011)  ;; unused state

(reset0  . #v11100)  ;; reset state, make ALU generate a zero
(reset1  . #v11101)  ;; write zero in address latch, data output, etc.
(reset2  . #v11110)  ;; zero all 16 registers in register file
(v11111  . #v11111)  ;; unused state
))
```

The macro `DEFINE-CONTROL-STATES` is used to create a number of Nqthm events that "implement" the table above in the Nqthm logic. For each major control state it submits six events which define two constants, such as the six shown here for the first state.

```
(DEFN V_FETCH0 NIL (LIST F F F F F))
(DISABLE V_FETCH0)
(DISABLE *1*V_FETCH0)

(DEFN N_FETCH0 NIL (V-TO-NAT (LIST F F F F F)))
(DISABLE N_FETCH0)
(DISABLE *1*N_FETCH0)
```

Next, a `DEFTHEORY` event defines a theory `VECTOR-STATE-THEORY` that contains the names of all the "`V-`" functions just defined, such as `V-FETCH0` from the display above, and then a second `DEFTHEORY` event defines a theory `NATURAL-STATE-THEORY`

that contains the names of all the "N-" functions just defined, such as N-FETCH0 from the display above. These two events are followed by a lemma BVP-LENGTH--STATE-VECTORS that defines two rewrite rules for each major control state, such as the following two for the FETCH0 state.

```
(EQUAL (LENGTH (V_FETCH0)) 5)
(BVP (V_FETCH0))
```

Finally, the lemma just proved is disabled.

The macro DEFINE-CONTROL-STATE-ACCESSORS, also defined in "control.lisp" and used in the file "control.events", defines accessors for the control state, and concludes with a DEFTHEORY event that creates a theory containing these accessors. It macroexpands as follows (many lines omitted, as shown):

```
(PROGN
  (DEFN RW- (CNTL-STATE) (NTH 0 CNTL-STATE))
  (DISABLE RW-)
  (DEFN STROBE- (CNTL-STATE) (NTH 1 CNTL-STATE))
  (DISABLE STROBE-)
  ;; ... and so on for fields 2 through 14
  (DEFN ALU-ZERO (CNTL-STATE) (NTH 15 CNTL-STATE))
  (DISABLE ALU-ZERO)
  (DEFN STATE (CNTL-STATE) (SUBRANGE CNTL-STATE 16 20))
  (DISABLE STATE)
  ;; ... and so on
  (DEFN ALU-MPG (CNTL-STATE) (SUBRANGE CNTL-STATE 33 39))
  (DISABLE ALU-MPG)
  (DEFTHEORY CONTROL-STATE-ACCESSOR-THEORY
      (RW- STROBE- HDACK- WE-REGS WE-A-REG WE-B-REG WE-I-REG
           WE-DATA-OUT WE-ADDR-OUT WE-HOLD- WE-PC-REG DATA-IN-SELECT
           DEC-ADDR-OUT SELECT-IMMEDIATE ALU-C ALU-ZERO STATE
           WE-FLAGS REGS-ADDRESS ALU-OP ALU-MPG)))
```

Finally consider the third of the three macros mentioned above, DEFINE--CONTROL-VECTOR-FUNCTIONS. It is used to define functions that are used to transition to the major control states defined in the constant *CONTROL-STATES* displayed above. Before we give an example of such a definition, let us look at two more constants from the Lisp file "control.lisp".

Recall that the major control state is just 5 bits of the 40-bit control vector. Our finite state machine will not only take us from a given 5-bit major control state to a new state, but will also supply values for the other fields in the 40-bit control

vector. The following table supplies the default values for fields of the control vector. That is, below we describe a table *STATE-TABLE* that only displays the fields that take on other than the default values for all 40 bits of the control vector. We describe each of these fields later in this section.

```
(defconstant
  *control-template*
  ;; Line       Type (Bit/Vector)  Default
  '((rw-                  b          t)
    (strobe-              b          t)
    (hdack-               b          t)
    (we-regs              b          f)
    (we-a-reg             b          f)
    (we-b-reg             b          f)
    (we-i-reg             b          f)
    (we-data-out          b          f)
    (we-addr-out          b          f)
    (we-hold-             b          f)
    (we-pc-reg            b          f)
    (data-in-select       b          f)
    (dec-addr-out         b          f)
    (select-immediate     b          f)
    (alu-c                b          (carry-in-help
                                       (cons c (cons f op-code))))
    (alu-zero             b          f)
    (state                5          #v00000)
    (we-flags             4          (make-list 4 f))
    (regs-address         4          pc-reg)
    (alu-op               4          op-code)
    (alu-mpg              7          (mpg
                                      (cons f
                                            (cons f op-code))))))
```

Now we can describe the transitions from each of the major control states. These are also given as state transition diagrams in Figures 10.3 through 10.9. These state diagrams are described symbolically by the constant *STATE-TABLE*, which is defined in the file "control.lisp". Each entry in this table indicates the current major control state (as named in the constant above *CONTROL-STATES*), the next major control state, and zero or more specifications of settings for the other fields in the control state. To repeat, each entry in *STATE-TABLE* specifies for each major control state what the next 40-bit control state is to be (of which five bits indicate the next major control state). Some of these specifications are just field names specified by the constant *CONTROL-TEMPLATE*, indicating that

we are to use the negation of the default specified by that constant. This negation approach does not work for fields of bits. There are entries of the form `(field term)`, indicating that `term` is to be the non-default value for `field`. Here then is a portion of our specification of the control algorithm for the FM9001.

```
(defconstant
  *state-table*
  '((fetch0 fetch1 we-addr-out we-a-reg (regs-address pc-reg)
            (rw- rw-) we-hold-
            alu-zero
            (alu-op (alu-inc-op))
            (alu-c (carry-in-help (cons c (cons t (alu-inc-op)))))
            (alu-mpg (mpg (cons t (cons f (alu-inc-op))))))

    (fetch1 (if hold- fetch2 hold0))

    (fetch2 fetch3 strobe-
            we-regs (regs-address pc-reg)
            (alu-c (carry-in-help (cons c (cons f (alu-inc-op)))))
            (alu-op (alu-inc-op))
            (alu-mpg (mpg (cons f (cons f (alu-inc-op))))))

    ..... many entries omitted .....

    (reset2 (if all-t-regs-address fetch0 reset2)
            we-regs
            alu-zero
            (alu-op (alu-inc-op))
            (alu-c (carry-in-help (cons c (cons t (alu-inc-op)))))
            (alu-mpg (mpg (cons t (cons f (alu-inc-op)))))
            (regs-address (v-inc regs-address)))

    (v11111 reset0)))
```

Let us describe a couple of the transitions represented by this table. Consider the initial major state, `fetch0`. The first entry in this table tells us that the next state will be `fetch1`, and that the remaining 35 fields of the control state vector will take on their default values *except* for the ones indicated in the entry in the table. So, for example, we see that `we-addr-out` and `we-a-reg` obtain the negations of their defaults shown in the constant `*CONTROL-STATES*` given earlier, while `regs-address` will attain the current value of `pc-reg` and `rw-` will retain its current value ... The entry for `reset2` is interesting because the next major

control state can be either `fetch0` or `reset2`, depending on the current value of `all-t-regs-address`. This branching aspect is illustrated at the bottom of Figure 10.9. From state `reset2`, if `REGS-ADDRESS` is 15 (actually a four-bit vector containing `T`'s), then we go to major state `fetch0`; otherwise, we go right back to major state `reset2`.

Remark. The above description is accurate for the finite state machine we have described. However, in the context of the entire chip one needs to be careful when reading `*STATE-TABLE*`. For instance, consider our `fetch0` example above. In particular, consider the entry `WE-ADDR-OUT`. Since the default for this field is `F`, this entry says that `WE-ADDR-OUT` is to take on the value `T` in the next control state. `WE-ADDR-OUT` controls when the 32-bit address output latch is to latch in a new value. Note however that the address latch is not affected until the following major control state (`fetch2`). This is because each new control state, as specified by `*STATE-TABLE*`, is stored in a 40-bit register, thus the new control bits do not affect the FM9001 microarchitecture until the following major state. This "pipelining" of the control logic was done in order to enhance testability of the chip. By using the built-in register scan chain, it is possible to set the control vector to any 40-bit value for testing purposes. However, this approach does reduce the performance of the machine, because we are forced to use one clock cycle for instruction decoding.

Let us return to discussion of the macro `DEFINE-CONTROL-VECTOR-FUNCTIONS`. This macro generates a definition of a specification function which computes the next 40-bit control state for each major control state shown in `*STATE-TABLE*`. Thus, for each major control state the macro creates a definition of the transition function. Each generated definition takes the arguments shown below (note that `I-REG` holds the current instruction, which provides a lot of information), and computes the control vector for each major control state. This macro also creates a "destructuring" lemma describing the components of that next control state vector, and it disables both the definition and the lemma. It then disables both the definition and the lemma generated for each major control state. The macro `DEFINE-CONTROL-VECTOR-FUNCTIONS` also defines a couple of theories and proves that all of the next control vectors are bit vectors, and then disables that lemma.

The next major section of "control.events" defines the module `CONTROL-LET`, which can be seen in Figure 10.2. This function is a "helper function" that defines twelve values used in the computation of the next control vector. The definition of the `CONTROL-LET` module is completed by the two macro calls:

```
(module-predicate control-let*)

(module-netlist control-let*)
```

The logic for the module `NEXT-STATE` is synthesized from the `*STATE-TABLE*`, defined above. The output of the `NEXT-STATE` module is a 32-bit vector, of which only one bit is `T`, indicating what next major control state the machine should enter.

The module CV produces the 40-bit control vector. It does this by using the inputs from the CONTROL-LET and NEXT-STATE modules and the instruction register I-REG, the four-bit pointer to the register containing the program counter PC-REG, and the four-bit register REGS-ADDRESS, which is used to specify the register in the register file is to be accessed. The hardware module CV takes the 32-bit, one-hot encoding of the next major control state and other inputs to produce the next 40-bit control vector. Note that CV is a part of NEXT-STATE, which actually provides the 40-bit control vector.

We now describe each of the 40 bits of the control vector. These bits are computed in module CV, which is the last module of NEXT-CNTL-STATE. These bits are computed combinationally, and are stored each clock cycle in a 40-bit register. Thus, they do not affect the operation of the microarchitecture until the following clock cycle.

- RW- — memory read/write control
- STROBE- — memory strobe
- HDACK- — hold acknowledgement
- WE-REGS — enable write into the register file
- WE-A-REG — enable write into A-REG
- WE-B-REG — enable write into B-REG
- WE-I-REG — enable write into I-REG
- WE-DATA-OUT — enable write into DATA-OUT
- WE-ADDR-OUT — enable write into ADDR-OUT
- WE-HOLD- — enable write into the HOLD- input register
- WE-PC-REG — enable write into the PC-REG input register
- DATA-IN-SELECT — selects input source for A-REG, B-REG, and I-REG
- DEC-ADDR-OUT — selects whether to decrement value destined for ADDR-OUT register
- SELECT-IMMEDIATE — controls whether nine-bit immediate value is used
- ALU-C — input carry to the ALU
- ALU-ZERO — forces ALU output to all F values
- STATE — five-bit major control state
- WE-FLAGS — four-bit write enable for each of the FLAGS

- `REGS-ADDRESS` — four-bit value specifying register in register file to use for read or write
- `ALU-OP` — four-bit value specifying principal `ALU` operation
- `ALU-MPG` — seven-bit value specifying `ALU` operation

The module `NEXT-CNTL-STATE` glues together the four modules `CONTROL-LET`, `DECODE-5`, `NEXT-STATE`, and `CV` to produce the 40-bit control vector. This is shown in Figure 10.2. The logic for the entire contents of Figure 10.2 is purely combinational.

Perhaps it would be useful to trace through the major control states reached when a particular instruction is executed. First consider the decoding of an arbitrary instruction. The state names used correspond to those given earlier in the constant `*CONTROL-STATE*` presented earlier in this section. To execute an instruction, we always start in major control state `FETCH0` (see the top circle in Figure 10.3), where we move the program counter address to the `ADDR-OUT` register in anticipation of reading an instruction from memory. We move the program counter address to the `A-REG` so we can increment this address. We also sample the `HOLD-` input, which is tested subsequently in state `FETCH1`. If a `HOLD-` is asserted, then we procede to major control state `HOLD0`. Otherwise, we proceed to state `FETCH2`, where we store the incremented program counter back into the register file and assert the external memory strobe line, `STROBE-`. We now proceed to state `FETCH3`, where we wait for `DTACK-` to be asserted. At the termination of state `FETCH3`, we load the instruction register `I-REG` with the value read from memory. We now have the instruction to be executed in `I-REG`.

We are now ready to "decode" the instruction, and one of six major control states is selected, depending upon the type of instruction. This is shown at the bottom of Figure 10.3. Notice that the righthand-most branch contains the next major control state destination `FETCH0`, which is a "no-op" instruction. The other five target major control states are picked depending on the nature of the instruction. These different states are selected depending upon whether the instruction is binary or unary, whether the A-operand is register-direct or register-indirect, and, in the case of memory-indirect addressing, whether the register specified by the A-operand should be pre-decremented. Figures 10.4 through Figures 10.8 contain the details for executing the various instructions. Figure 10.9 contains the `HOLD-` acknowledge control algorithm and the reset control algorithm.

See Section 14.58 for the event file "control-events.events".

10.4 REGFILE

A high-level view of the FM9001 register file is given in Figure 10.10. When the write-enable line `WE` is set, the `DATA` vector is latched into the register file at the

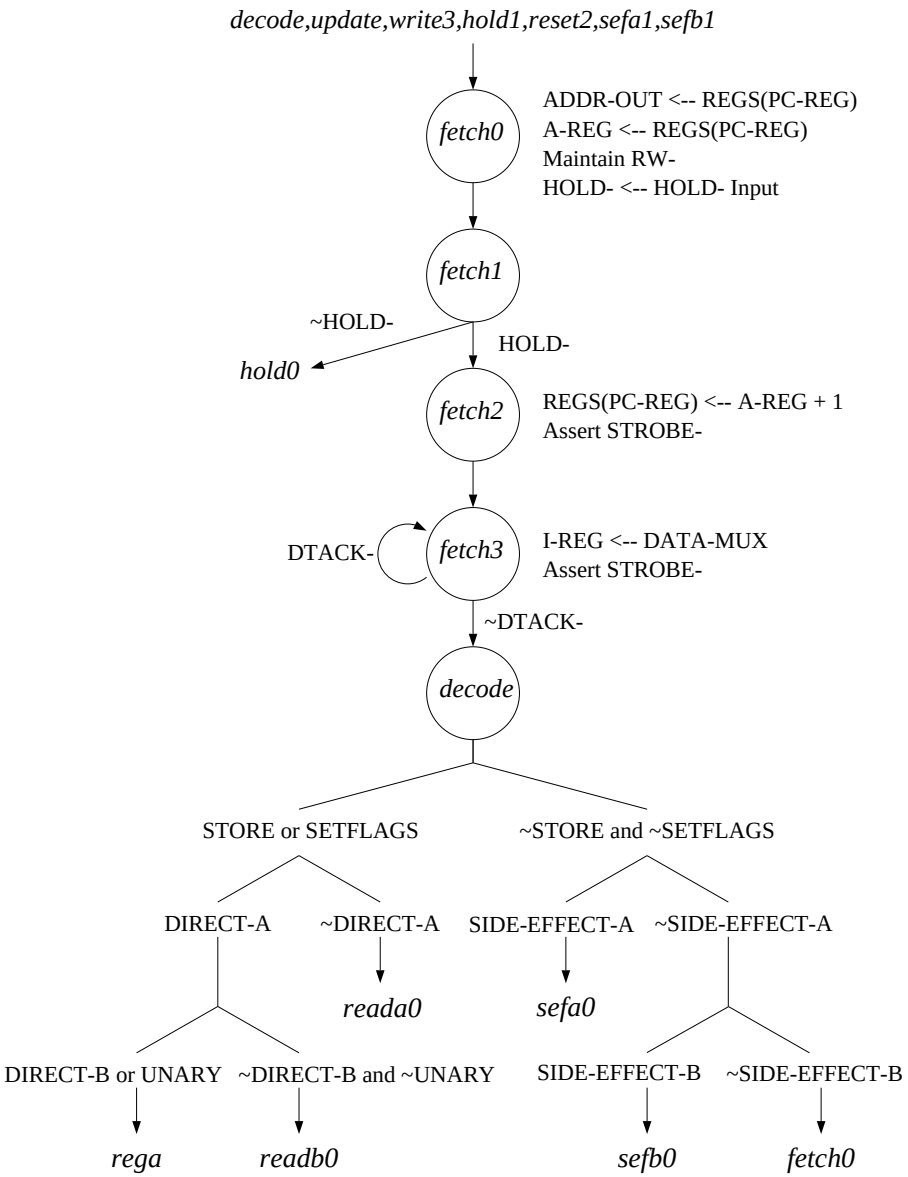

Figure 10.3: Major Control State Diagram 0

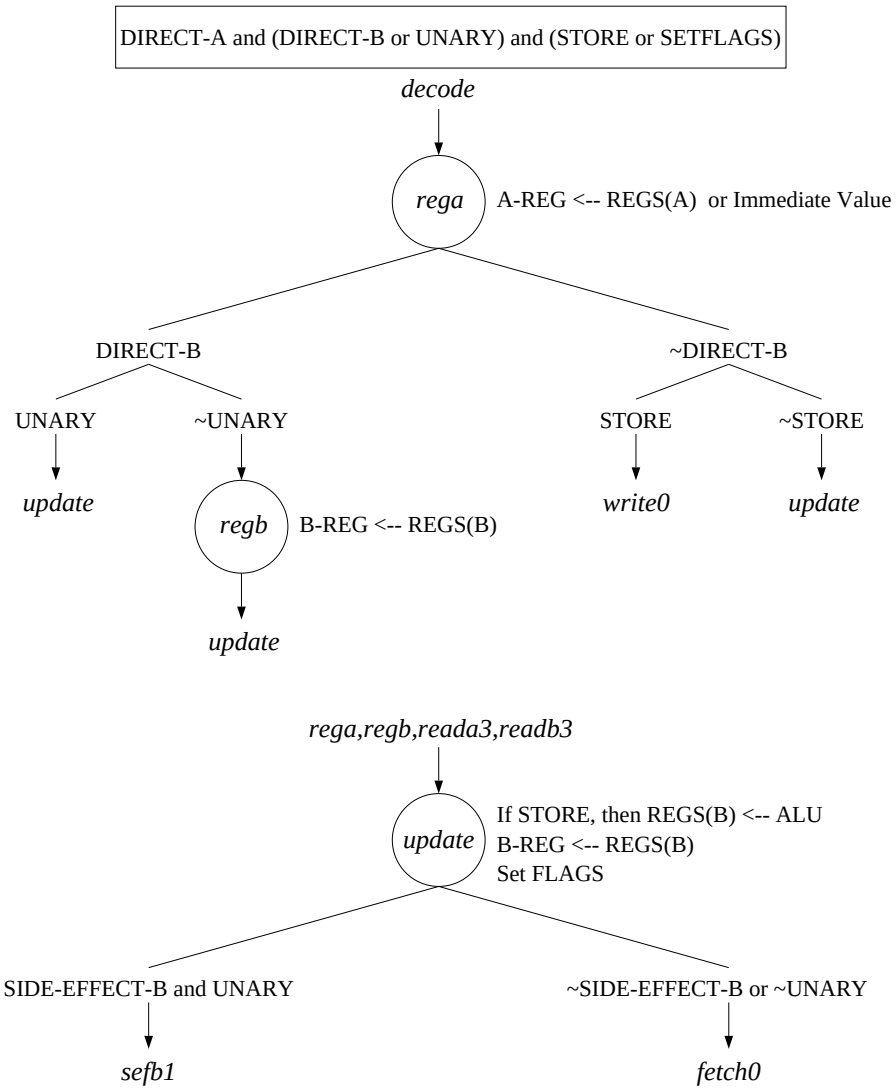

Figure 10.4: Major Control State Diagram 1

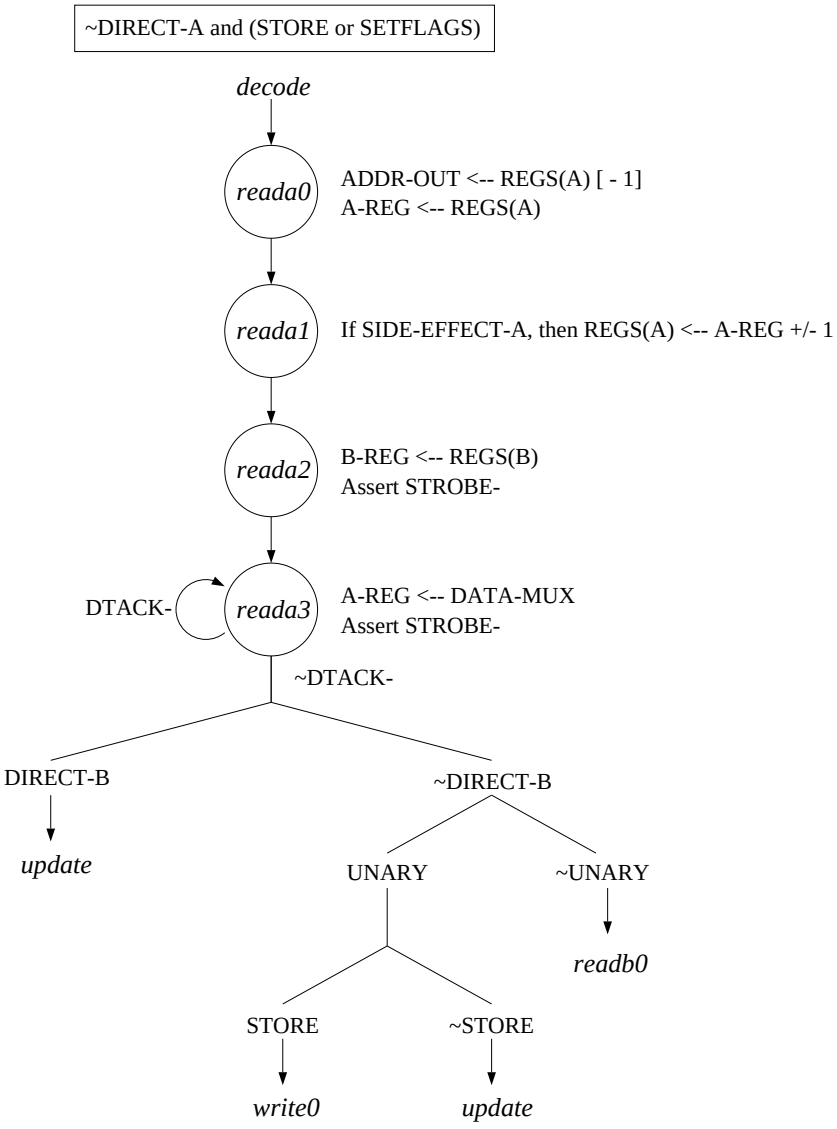

Figure 10.5: Major Control State Diagram 2

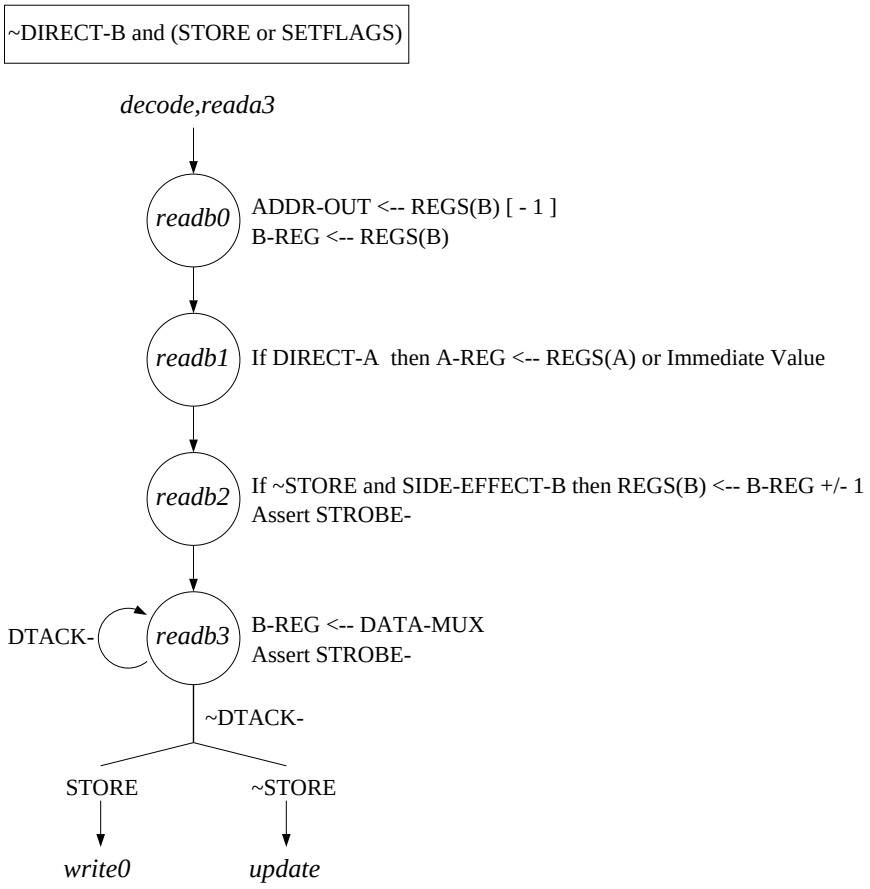

Figure 10.6: Major Control State Diagram 3

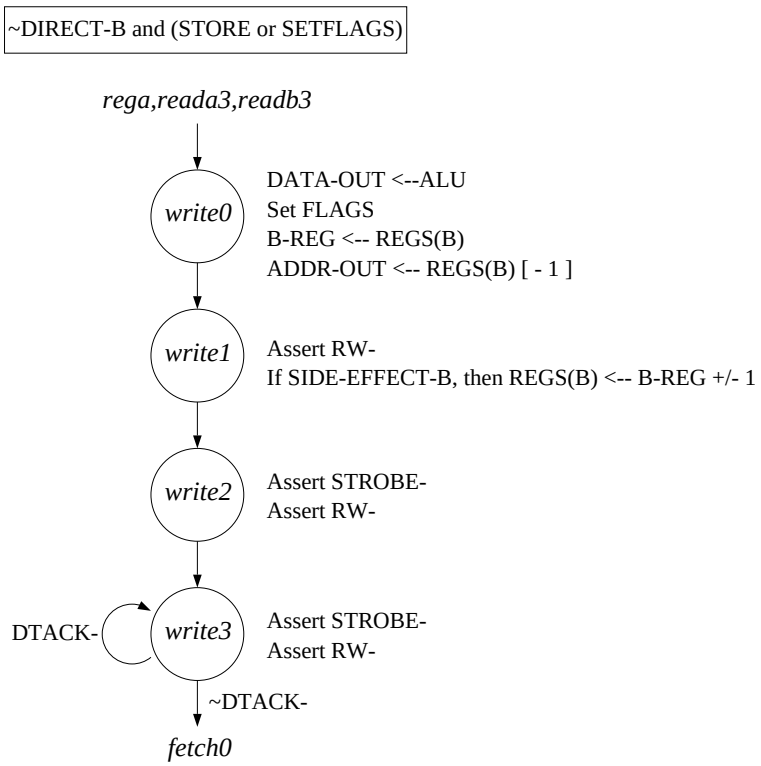

Figure 10.7: Major Control State Diagram 4

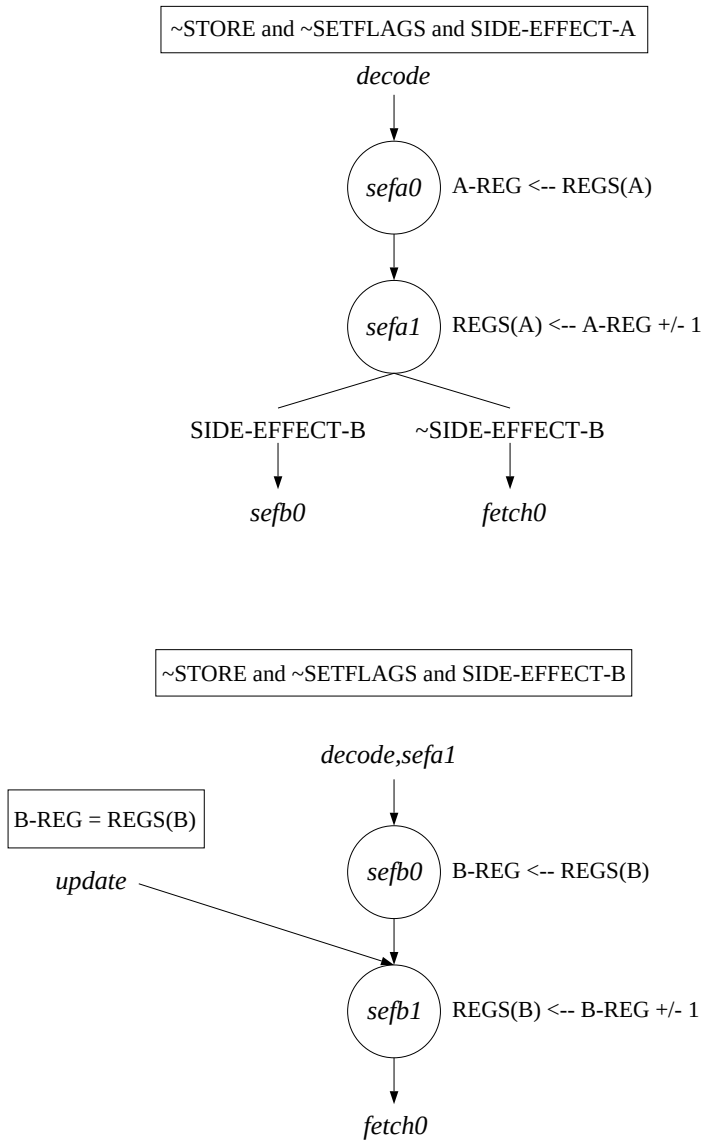

Figure 10.8: Major Control State Diagram 5

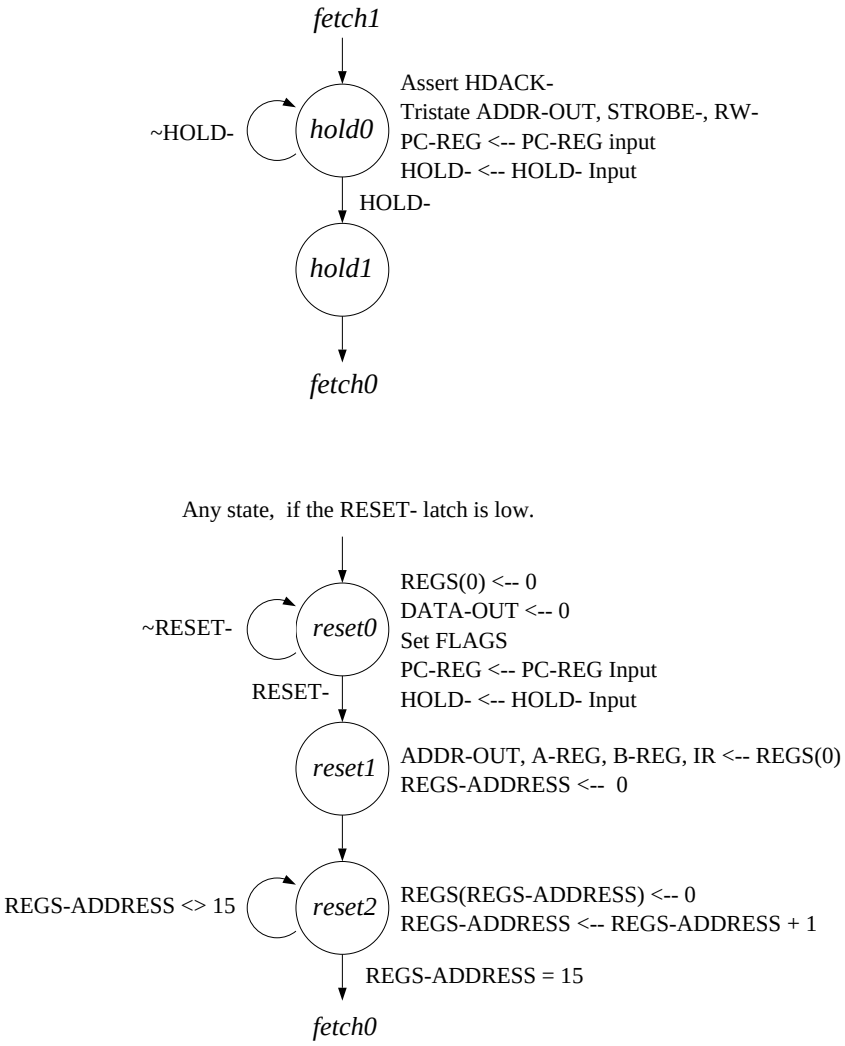

Figure 10.9: Major Control State Diagram 6

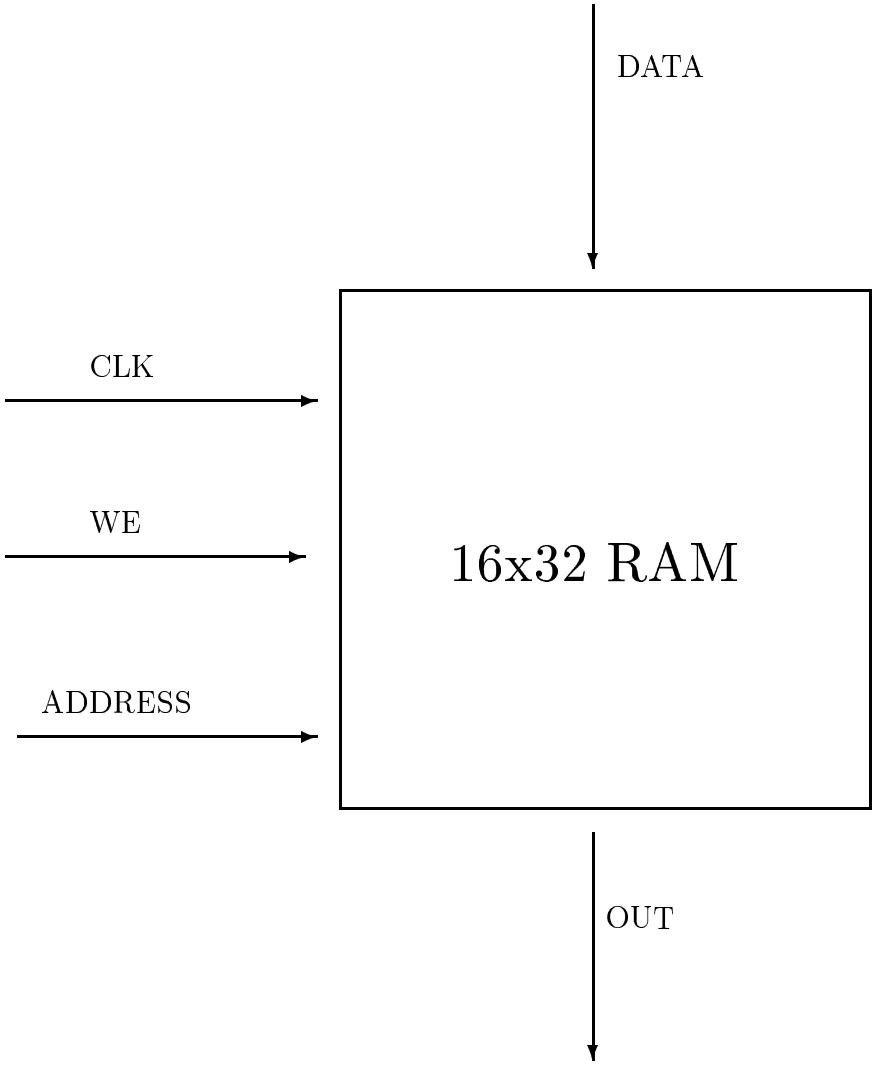

Figure 10.10: FM9001 Register File

address `ADDRESS`. The register file can only be read or written each clock cycle (not both).

In order to save space on the chip, we chose to use a level-sensitive RAM to implement the register file. We have surrounded this RAM with several 32-bit latches, in order to make our edge-triggered model of state faithful to the "snapshot" semantics embodied by `DUAL-EVAL`, as described in Section 5.1. Figure 10.11 is a more detailed schematic for the register file that displays the various latches. Note that the level-sensitive RAM takes a clock cycle in order to store input data, which means that we need to take special care when attempting to read data from a register that is currently being written. Therefore we use a comparator and a multiplexor to allow accurate "reading" of the data stored during the prior clock cycle.

Let us take a look at the Boolean behavioral specifications of the read and write operations for the register file. The read operation follows the description above: if the address agrees with the previous clock cycle's address that was latched in at that time, and we are currently performing a write operation, then we need to pass the data straight through to the output; otherwise, we simply get the value from the level-sensitive RAM.

Definition.

```
(read-regs address regs)
  =
(let ((regfile      (car regs))
      (last-we      (cadr regs))
      (last-data    (caddr regs))
      (last-address (cadddr regs)))
  (if (and last-we (v-iff address last-address))
      last-data
    (read-mem address regfile)))
```

The behavioral specification of the write operation returns a new state, where the state contains four components: the new RAM, the latched-in write-enable value, and the appropriate data and address values.

Definition.

```
(write-regs we address regs data)
 =
(let ((regfile      (car regs))
      (last-we      (cadr regs))
      (last-data    (caddr regs))
      (last-address (cadddr regs)))
  (list (if last-we
            (write-mem last-address regfile last-data)
          regfile)
        we
```

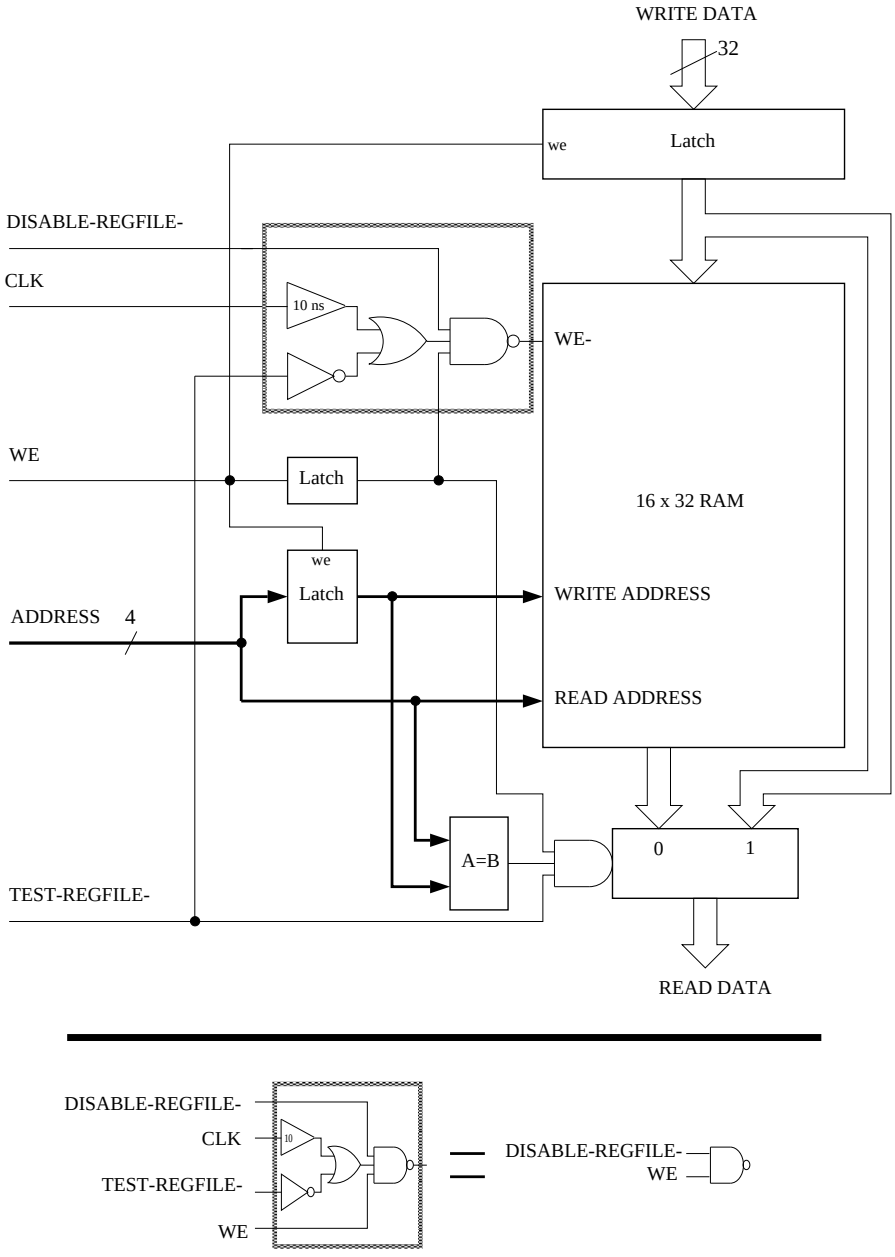

Figure 10.11: A Detailed View of the FM9001 Register File. Serial scan interconnections are not shown. The `DUAL-EVAL` model of the boxed circuit is a special NAND gate primitive, `RAM-ENABLE-CIRCUIT`.

```
        (if we data last-data)
        (if we address last-address)))
```

Our implementation of the register file is produced using the `MODULE-GENERATOR` macro (see Section 2.6). If we were to build what we want in the most straightforward way, the clock would be an input to a delay gate, yet our top-level predicate does not allow clock signals to be used in that way. Therefore, we provide an artificial primitive called `RAM-ENABLE-CIRCUIT` that provides the desired clocking for the level-sensitive RAM. However, our translator to LSI Logic's Network Description Language (NDL) includes special code to generate an implementation in actual gates rather than a reference to our artificial primitive. This primitive, preceded by a comment explaining its implementation in gates, may be found (of course) in the primitives file, "primp-database.lisp" (see Section 2.9).

See Section 14.59 for the event file "regfile.events".

10.5 FLAGS

This file defines the hardware for updating the flags and proving the usual value and state theorems. We use a scan latch primitive `FD1SLP` for each flag for easier testing.

See Section 14.60 for the event file "flags.events".

10.6 EXTEND-IMMEDIATE

The `EXTEND-IMMEDIATE` module sign-extends a 9-bit input vector to a 32-bit vector. This module is required for the case that the machine instruction indicates that the A operand is to be used as immediate data; see Section 9.1.

See Section 14.61 for the event file "extend-immediate.events".

10.7 PAD-VECTORS

Signal strengths inside the chip are smaller than the strengths on the external input and output lines. The various I/O pad devices provide an appropriate interface.

In this file we define n-bit module generators for four types of I/O pads: `TTL-INPUT`, `TTL-OUTPUT`, `TTL-TRI-STATE-OUTPUT`, and `TTL-BIDIRECTIONAL`. For example, a group of three `TTL-INPUT` pads is defined as follows. We use the function `LISP-NETLIST` (see Section 5.9) to make the result more readable.

```
(lisp-netlist (ttl-input-pads* 3))
 =
'(TTL-INPUT-PADS_3 (PI IN_0 IN_1 IN_2)
                   (PO_2 B-OUT_0 B-OUT_1 B-OUT_2)
```

```
((G_0 (OUT_0 PO_0) TTL-INPUT (IN_0 PI))
 (B_0 (B-OUT_0) B-BUF (OUT_0))
 (G_1 (OUT_1 PO_1) TTL-INPUT (IN_1 PO_0))
 (B_1 (B-OUT_1) B-BUF (OUT_1))
 (G_2 (OUT_2 PO_2) TTL-INPUT (IN_2 PO_1))
 (B_2 (B-OUT_2) B-BUF (OUT_2)))
NIL)
```

Actually, the `B-BUF` buffers are an artifact of LSI Logic's software. A module must contain at least one internal gate on the inside; it may not consist entirely of pads. Buffers are placed on every pad data output, instead of on just one pad output, so that the timing for all input pads is similar. The outputs `PO_0`, `PO_1`, and `PO_2` are parametric pad outputs that are used for post-manufacture testing of the input pads.

See Section 14.62 for the event file "pad-vectors.events".

10.8 FM9001-HARDWARE

We are now almost ready to build the chip system (chip with memory) using the modules that we have been defining. First, however, we specify the behavior of the chip system under normal operating conditions. Thus, we assume that the test lines `TE`, `DISABLE-REGFILE-` and `TEST-REGFILE-` are inactive. The theorem that makes these assumptions and equates the chip system's operation with its behavioral specification is found in the next section, Section 10.9. Thus (ironically), in spite of its name, this is the only file in the present chapter that does not actually define hardware.

The low-level (four-valued logic) specification of the chip's operation under non-test conditions is given by the following function.

Definition.

```
(run-fm9001 state oracle n)
 =
(if (zerop n)
    state
  (run-fm9001 (fm9001-next-state state (car oracle))
              (cdr oracle)
              (sub1 n)))
```

The following lemma has analogues in many interpreter proofs.

Theorem. `RUN-FM9001-PLUS`

```
(equal (run-fm9001 state oracle (plus n m))
       (run-fm9001 (run-fm9001 state oracle n)
                   (nthcdr n oracle)
                   m))
```

This file also has a number of lemmas stating basic structural properties of the chip state.

See Section 14.63 for the event file "fm9001-hardware.events".

10.9 CHIP

This file glues together the hardware modules we have created so far and creates the final chip system (chip with memory), in the following three stages.

- `CHIP-MODULE`: The entire internal logic of the chip, but without the I/O pads.
- `CHIP`: The entire chip, including the I/O pads.
- `CHIP-SYSTEM`: The entire chip, bus, and memory system.

Documentation appears in the file "chip.events". For all three of these modules we prove lemmas stating the equivalence of the `DUAL-EVAL` semantics of the modules with low-level structural-style specifications.

There are a number of unusual (but important) lemmas that are used as hints. For example, the following lemma tells the theorem prover how to write a list as an explicit call of `APPEND` on appropriate sublists.

Theorem. `EQUAL-LENGTH-40-AS-COLLECTED-NTH+SUBRANGE`

```
(implies
 (and (equal (length l) 40)
      (properp l))
 (equal l (append (list-as-collected-nth l 16 0)
                  (subrange l 16 39))))
```

The file concludes with the following theorem, which is the main theorem in the file. It says that under certain hypotheses (to be explained below), the result of running `DUAL-EVAL` for `N` steps from an appropriate initial `STATE`, using an appropriate oracle `INPUTS`, agrees with our low-level (four-valued) specification function `RUN-FM9001`.

Theorem `CHIP-SYSTEM=RUN-FM9001`

```
(implies
```

```
(and (chip-system& netlist)
     (fm9001-state-structure state)
     (chip-system-invariant state)
     (chip-system-operating-inputs-p inputs n)
     (equal fm9001-inputs (map-up-inputs inputs)))
(equal (simulate-dual-eval-2 'chip-system inputs state netlist n)
       (run-fm9001 state fm9001-inputs n)))
```

This theorem states that the netlist level implements the four-valued level, as illustrated in Figure 1.1. Because of this theorem, we can turn our attention to proving the equivalence of the low-level specification function `RUN-FM9001`, which does not mention any netlists but is purely "logical," with a higher-level specification function. Thus, we have proven that the structural definition of the FM9001 does indeed implement a more abstract, but still low-level specification function.

We now explain the hypotheses of the theorem above. The first ones are simple. `(CHIP-SYSTEM& NETLIST)` says that `NETLIST` contains our definition of the FM9001 netlist, including the memory and interconnection bus. The conjunction of the predicates `(FM9001-STATE-STRUCTURE STATE)` (cf. Section 10.8) and `(CHIP-SYSTEM-INVARIANT STATE)` says that the state has the right shape.

This file also defines certain properties of the `CHIP-SYSTEM`'s state and the input oracle, which is just a list of input vectors for the `CHIP-SYSTEM`; see the discussion of the `INPUTS` argument to `SIMULATE-DUAL-EVAL-2` near the end of Section 5.1. We assume that the test lines are disabled and the register file is enabled by assuming that `CHIP-SYSTEM-INPUT-INVARIANT` holds.

Definition.

```
(chip-system-input-invariant inputs)
 =
(let ((clk              (car inputs))
      (ti               (cadr inputs))
      (te               (caddr inputs))
      (reset-           (cadddr inputs))
      (hold-            (caddddr inputs))
      (disable-regfile- (cadddddr inputs))
      (test-regfile-    (caddddddr inputs))
      (pc-reg-in        (cdddddddr inputs)))
  (and (equal te f)
       (equal disable-regfile- t)
       (equal test-regfile- t)
       (properp pc-reg-in)
       (equal (length pc-reg-in) 4)))
```

Now we are ready to explain the next hypothesis `(CHIP-SYSTEM-OPERATING--INPUTS-P INPUTS N)`. It says that each input vector in the oracle satisfies the predicate whose definition is displayed just above.

Finally, we need the notion of "mapping up" an oracle. The low-level oracle supplies an input vector for the `CHIP-SYSTEM` at each clock tick, and so does the higher-level oracle. The difference is that the higher-level oracle does not contain any test inputs. This makes sense, since our theorem assumes (with `CHIP-SYSTEM-INPUT-INVARIANT`) that the chip system is operating in a non-test mode, and hence the test lines are not appropriate for the higher-level oracle. Thus, in effect, we have proven that the test logic does not interfere with the "normal" operation of the chip.

See Section 14.64 for the event file "chip.events".

Chapter 11

CORRECTNESS OF THE FM9001

The most important theorems proved about the FM9001 are contained in the following files:

- "proofs.events" — the principal result that the netlist implements the high level
- "approx.events" — the monotonicity of the `DUAL-EVAL` HDL
- "final-reset.events" — that the processor can be reset and a more refined version of lemmas from "proofs.events"
- "well-formed-fm9001.events" — that the netlist is well-formed
- "alu-interpretation.events" — correctness of the ALU with respect to natural number and integer operations
- "flag-interpretation.events" — correctness of arithmetic flag results
- "more-alu-interpretation.events" — refinements of "alu-interpretation.events"

These files and several others are discussed in the next three chapters.

11.1 EXPAND-FM9001

Recall that `FM9001-NEXT-STATE` is the single-step function for the FM9001 low-level (four-valued level) interpreter, `RUN-FM9001`.

In order to prove that the control logic in the FM9001 correctly executes machine instructions, we prove rewrite rules that, in essence, step the low-level machine. That is, we prove rewrite rules to allow the prover to symbolically execute

the low-level machine from any major control state to the major control states that follow. Consider, for example, the first of these forms:

```
(STEP-FM9001 FETCH0 :SUFFIX 0)
```

which submits the large event `FETCH0$STEP0` to the prover.

We submit a number of such symbolic single-step simulations to the prover. Then we prove, by induction, for each place in the state diagrams where a one-cycle loop exists, that we can wait in this loop for an indeterminate amount of time. After proving all the single-step lemmas for the major control states, we combine them into multi-step simulations. We know of no other microprocessor verification where it has been proven that arbitrary delays by the memory are acceptable.

See Section 14.65 for the event file "expand-fm9001.events".

11.2 PROOFS

The first part of this file establishes, in lemma `FM9001-INTERPRETER-CORRECT`, that the four-valued level implements the Boolean user-level description of the FM9001. This proof makes heavy use of the "chunk" simulations performed by the lemmas in the file "expand-fm9001.events" (see Section 11.1).

```
Theorem.  FM9001-INTERPRETER-CORRECT

(let ((clock-cycles (total-microcycles state inputs instructions)))
  (implies
   (and (fm9001-state-structure state)
        (macrocycle-invariant state pc)
        (operating-inputs-p inputs clock-cycles))
   (equal (map-up (run-fm9001 state inputs clock-cycles))
          (FM9001-interpreter (map-up state) pc instructions))))
```

We now paraphrase the preceding theorem. The function `TOTAL-MICROCYCLES`, given the current state of the machine, the machine inputs, and the number of instructions to be executed, computes how many low-level steps (clock cycles) are required by the four-valued level interpreter, `RUN-FM9001`, to complete the same number of user-level instructions.

The predicate `FM9001-STATE-STRUCTURE` insures that the `STATE` is well formed. The `MACROCYCLE-INVARIANT` predicate is an invariant about the state of the machine at the beginning of the instruction execution cycle: all of the internal registers are Boolean and properly sized; the machine is in state `FETCH1` (ready to execute

an instruction); the ADDR-OUT register contains the program counter; there are no pending writes in the register file; HOLD- and RESET- are not asserted; the PC-REG is equal to (and remains equal to) the specified PC; and the memory is well-formed and in a quiescent state. This is an important invariant; one of the more important proofs that follows states that if we begin in this state, and run for (MICROCYCLES STATE), then we will reach a state recognized by this invariant. This is the basis for the inductive proof that the four-valued level machine implements the behavioral specification.

The predicate OPERATING-INPUTS-P recognizes those four-valued level input streams that do not reset the machine and that do not include hold requests. The function MAP-UP converts a four-valued level state to a user-level state.

The conclusion states that running the four-valued interpreter RUN-FM9001 the proper number of clock cycles produces the same user-level state as the user-level specification FM9001-INTERPRETER.

The following theorem ties the above theorem together with the last theorem in the file "chip.events" to establish that the netlist level specification of the FM9001, when interpreted by the DUAL-EVAL simulator, implements the user-level specification.

```
Theorem.  CHIP-SYSTEM=FM9001-INTERPRETER

(let ((rtl-inputs (map-up-inputs inputs)))
  (let ((clock-cycles
         (total-microcycles state rtl-inputs instructions)))
    (implies
     (and (chip-system& netlist)
          (fm9001-state-structure state)
          (macrocycle-invariant state pc)
          (chip-system-operating-inputs-p inputs clock-cycles)
          (operating-inputs-p rtl-inputs clock-cycles))
     (equal
      (map-up (simulate-dual-eval-2
               'chip-system inputs state netlist clock-cycles))
      (fm9001-interpreter (map-up state) pc instructions)))))
```

The theorem above is the first of a number of similar statements that the FM9001 user-level specification is indeed implemented by the netlist design. Looking back at Figure 1.1, this theorem states that "the diagram commutes," i.e., speaking in informal programmer's jargon, if one starts with a low-level state, maps it up to a high-level state, and runs the user-level FM9001 specification on that state thereby obtaining a final state, one may also obtain the same final state by instead simulating the FM9001 netlist using DUAL-EVAL on the initial low-level state and then mapping that result up. The preceding sentence

ignores the issues of external memory responses. Let us now review the hypotheses and conclusions of CHIP-SYSTEM=FM9001-INTERPRETER less informally. Let RTL-INPUTS be the external inputs to the FM9001 after stripping out the test inputs. Further, let CLOCK-CYCLES be the number of clock cycles required by the microarchitecture to complete the number of instructions specified by the natural number INSTRUCTIONS. The first hypothesis (CHIP-SYSTEM& NETLIST) requires that NETLIST contain the netlist for the entire microprocessor and memory system. The second hypothesis requires that the low-level state be well formed; we later prove that the reset process will produce such a state. The third hypothesis, (MACROCYCLE-INVARIANT STATE PC), requires that all of the internal registers be Boolean and properly sized; the machine be in state FETCH1 (ready to execute an instruction); the ADDR-OUT register contain the program counter; that there be no pending writes in the register file; that HOLD- and RESET- are not asserted; that PC-REG be equal to (and remain equal to) the specified PC; and that the memory be well-formed and in a quiescent state. The fourth hypothesis, (CHIP-SYSTEM-OPERATING-INPUTS-P INPUTS CLOCK-CYCLES), stipulates that test inputs to the FM9001 are disabled. The last hypothesis, (OPERATING--INPUTS-P RTL-INPUTS CLOCK-CYCLES), requires that the external reset and hold signals remain disabled.

In the conclusion, the function MAP-UP converts a well-formed FM9001 netlist-level state to a user-level state. SIMUALTE-DUAL-EVAL-2 repeatedly applies DUAL--EVAL to simulate the netlist. FM9001-INTERPRETER is the behavioral level specification for the FM9001; this is the arrow named "Boolean Interpretation" in Figure 1.1. We later prove that the arrows named "Integer Interpretation" and "Natural Number Interpretation" are equivalent to the "Boolean Interpretation" arrow (see Chapter 13).

Here is an informal statement of the chief result proved about the FM9001. Let h be the hardware netlist that we have constructed for the FM9001. We have proved that for each FM9001 user-visible state, s, and for each positive integer, n, there exists a positive integer c such that the result of running the user-model of the FM9001 (the function FM9001) n steps can instead be obtained by simulating h and s under the DUAL-EVAL semantics for c steps. In precisely stating the theorem, we arrange to supply the DUAL-EVAL semantics with a transform (obtained with MAP-DOWN) of s, and afterwards we do a reverse transformation (with MAP-UP) to obtain the final user-visible state. Futhermore, in making the statement precise we stipulate that the external stimuli, i, to the chip do not enable a hold, a reset, or a test input for the c clock cycles. The fact that n and c are different reflects the fact that a single FM9001 instruction takes several clock cycles to implement at the DUAL-EVAL netlist level. The precise statement of this correctness result is:

```
Theorem.  FM9001=CHIP-SYSTEM-SUMMARY

(let ((h (chip-system$netlist))
      (c (total-microcycles (map-down s) (map-up-inputs i) n)))
```

```
(implies
 (and (fm9001-statep s)
      (no-holds-reset-or-test i c))
 (equal
  (fm9001 s n)
  (map-up
   (simulate-dual-eval-2 'chip-system i (map-down s) h c)))))
```

This theorem is the final event of the file "proofs.events". See the file "final-reset.events" for a set of lemmas that prove that such a state can be reached as a result of the reset process.

11.3 APPROX

An important property of the FM9001 is that a specified *reset sequence* of input vectors puts the FM9001 in an appropriate specified initial state. The proof of this property can be done by direct simulation if one views the `(X)` value as truly representing the 'unknown' value, because if one can show that the reset sequence produces the desired effect starting with an initial state of all `(X)` values, then it ought to produce the desired effect starting with *any* initial state. The point of the present event file is to show that in fact, it really does suffice to consider an initial state consisting of all `(X)` values in order to make the desired conclusion about an arbitrary initial state. A more complete description of this event file may be found in Kaufmann's "A Hardware Reset Lemma and Its Proof"[18].

In order to motivate what follows, let us begin by considering what our four-valued logic functions return when some of their inputs are the "unknown" value, `(X)`. In elementary mathematics, we say that a function $f(x)$ is monotonic provided that

$$x \leq y \rightarrow f(x) \leq f(y)$$

If we think of the value `(X)` as being "strictly less-well defined" than the values `T` or `F`, then we can check that `F-AND`'s output is weakly more well-defined on input that is more weakly well-defined. In other words, `F-AND` is monotonic in both its arguments.

```
(f-and (X) T) = (X)

(f-and T T) =  T

(f-and (X) F) =  F

(f-and T F) = F
```

The preceding facts can be proved by mere execution, using `R-LOOP`.

Here is the final, cruical event in the file, followed by some comments.

```
Theorem.  XS-SUFFICE-FOR-RESET-LEMMA
(let ((final-1 (nth n (simulate fn inputs state-1 netlist)))
      (final-2 (nth n (simulate fn inputs state-2 netlist))))
  (implies (and (lessp n (length inputs))
                (s-approx state-1 state-2)
                (v-knownp (car final-1))
                (s-knownp (cadr final-1))
                (ok-netlistp 0 fn netlist '(mem-32x32)))
           (equal final-1 final-2)))
```

This lemma may be read as follows; we comment on the text of the lemma in order of appearance.

Consider two simulations whose final "snapshots" (see Section 5.1) are denoted `FINAL-1` and `FINAL-2` that start (respectively) from states `STATE-1` and `STATE-2`.

```
(let ((final-1 (nth n (simulate fn inputs state-1 netlist)))
      (final-2 (nth n (simulate fn inputs state-2 netlist))))
  ...)
```

Assume that we have a sequence `INPUTS` containing more than `N` input vectors.

```
(lessp n (length inputs))
```

Assume that `STATE-1` *approximates* `STATE-2`, roughly speaking in the sense that `STATE-2` may differ from `STATE-1` only by replacing some `(X)` values in `STATE-1` by any other values.

```
(s-approx state-1 state-2)
```

The result `FINAL-1` of the first simulation is actually a pair consisting of the final output vector together with the final state. With that in mind, we can view the next two assumptions as stating that the final output vector contains no `(X)` value and the final state also contains no `(X)` value.

```
(v-knownp (car final-1))
(s-knownp (cadr final-1))
```

Finally, assume that the netlist is syntactically well-formed, in the sense that all "leaf" modules are primitives, none of which is the memory primitive.

```
(ok-netlistp 0 fn netlist '(mem-32x32))
```

Then the two final output vectors are the same and the two final states are the same.

```
(equal final-1 final-2)
```

Let us sketch the strategy we use for proving the lemma above. The main idea is that the semantics given by `DUAL-EVAL` (cf. Section 5.1) is *monotone*. Consider the relation `B-APPROX` that holds between `(X)` and the other four-valued logic values, and also holds between any value and itself. More formally, we may say that a value is *known* if and only if it is either `T`, `F`, or `(Z)`. In particular, `(X)` is not 'known'. Then we formalize the notion of approximation for logic values as follows.

```
Definition.
(b-knownp x)
 =
(or (equal x t)
    (equal x f)
    (equal x (z))))

Definition.
(b-approx a1 a2)
 =
(if (b-knownp a1)
    (equal a1 a2)
  t))
```

This notion of approximation extends naturally to vectors (see the definition of `V-APPROX`) and state (see `S-APPROX`). Then the lemma `DUAL-EVAL-MONOTONE` says that `DUAL-EVAL` with flags 0 and 2 preserves the approximation ordering, as follows.

```
Lemma. DUAL-EVAL-MONOTONE  ;; slightly massaged
(implies (and (ok-netlistp flag fn netlist '(mem-32x32))
              (v-approx a1 a2)
              (s-approx s1 s2))
         (and (v-approx (dual-eval 0 fn a1 s1 netlist)
                        (dual-eval 0 fn a2 s2 netlist))
              (s-approx (dual-eval 2 fn a1 s1 netlist)
                        (dual-eval 2 fn a2 s2 netlist))))
```

It follows fairly easily from this lemma that simulation, i.e., the repeated application of DUAL-EVAL to a sequence of input vectors, is also monotone in an appropriate sense. Since "known" values can only approximate themselves, the lemma XS-SUFFICE-FOR-RESET-LEMMA shown at the start of this section follows readily.

Finally, we discuss briefly the idea of the proof of DUAL-EVAL-MONOTONE. The plan is to start by proving that the basic four-valued logic operators are monotone, then prove that the hardware primitives are monotone, and finally do the inductive proof that DUAL-EVAL is monotone. The file "monotonicity-macros.lisp" is quite helpful for the first two of these three steps, as we now show.

Consider the form (MONOTONICITY-LEMMAS (F-BUF F-AND)) from the present file, "approx.events". It creates the following lemmas, which say that the logic functions F-BUF and F-AND are monotone.

```
(PROVE-LEMMA F-BUF-MONOTONE (REWRITE)
  (IMPLIES (B-APPROX A1 A2)
           (B-APPROX (F-BUF A1) (F-BUF A2))))

(PROVE-LEMMA F-AND-MONOTONE (REWRITE)
  (IMPLIES (AND (B-APPROX A1 A2) (B-APPROX B1 B2))
           (B-APPROX (F-AND A1 B1) (F-AND A2 B2))))
```

Similar calls of the macro MONOTONICITY-LEMMAS create similar lemmas for the rest of the primitives, sometimes with hints. Consider for example the following form.

```
(monotonicity-lemmas (f-and3 f-and4) ((disable f-and b-approx)))
```

This creates lemmas for F-AND3 and F-AND4 analogous to the ones displayed above, but with the indicated DISABLE hint appended.

The next task is to prove monotonicity lemmas for the primitive state-holding hardware modules, except the memory. The macro constructed for this purpose is called PROVE-PRIMITIVE-MONOTONICITY. In this case, all primitive modules except the register file and the memory are handled by a single application of this macro. However, for illustrative purposes let us look at the events created by a call of this macro on just two primitives: (PROVE-PRIMITIVE-MONOTONICITY (B-AND FD1)). A quick perusal will show that this macro creates some rather sophisticated hints; these help the theorem prover perform the required proofs. The important lemmas below are B-AND-MONOTONE and FD1-MONOTONE, which say respectively that that a primitive two-input AND gate and a D flip-flop respect the approximation order. The notion MONOTONICITY-PROPERTY simply says that the approximation order is preserved, as in the statement of the lemma DUAL-EVAL-MONOTONE shown above.

```
(PROVE-LEMMA DUAL-EVAL-B-AND-VALUE (REWRITE)
  (EQUAL (DUAL-EVAL 0 'B-AND ARGS STATE NETLIST)
         (LET ((A (CAR ARGS)) (B (CAR (CDR ARGS))))
              (CONS (F-AND A B) 'NIL)))
  ((ENABLE DUAL-EVAL DUAL-APPLY-VALUE)))

(PROVE-LEMMA DUAL-EVAL-B-AND-STATE (REWRITE)
  (EQUAL (DUAL-EVAL 2 'B-AND ARGS STATE NETLIST) 0)
  ((ENABLE DUAL-EVAL DUAL-APPLY-STATE)))

(PROVE-LEMMA B-AND-MONOTONE (REWRITE)

           DUAL-EVAL-B-AND-STATE S-APPROX-IMPLIES-B-APPROX
           FOURP-IMPLIES-S-APPROX-IS-B-APPROX FOURP-F-BUF
           FOURP-F-IF)
   (EXPAND (V-APPROX A1 A2) (V-APPROX (CDR A1) (CDR A2)))))

(PROVE-LEMMA DUAL-EVAL-FD1-VALUE (REWRITE)
  (EQUAL (DUAL-EVAL 0 'FD1 ARGS STATE NETLIST)
         (LET ((D (CAR ARGS)) (CP (CAR (CDR ARGS))))
              (CONS (F-BUF STATE) (CONS (F-NOT STATE) 'NIL))))
  ((ENABLE DUAL-EVAL DUAL-APPLY-VALUE)))

(PROVE-LEMMA DUAL-EVAL-FD1-STATE (REWRITE)
  (EQUAL (DUAL-EVAL 2 'FD1 ARGS STATE NETLIST)
         (LET ((D (CAR ARGS)) (CP (CAR (CDR ARGS))))
              (F-BUF D)))
  ((ENABLE DUAL-EVAL DUAL-APPLY-STATE)))

(PROVE-LEMMA FD1-MONOTONE (REWRITE)
  (AND (MONOTONICITY-PROPERTY 0 'FD1 NETLIST A1 A2 S1 S2)
       (MONOTONICITY-PROPERTY 2 'FD1 NETLIST A1 A2 S1 S2))
  ((DISABLE-THEORY T)
   (ENABLE-THEORY GROUND-ZERO MONOTONICITY-LEMMAS)
   (ENABLE *1*B-APPROX *1*V-APPROX *1*S-APPROX V-APPROX
           MONOTONICITY-PROPERTY-OPENER-0
           MONOTONICITY-PROPERTY-OPENER-2 DUAL-EVAL-FD1-VALUE
           DUAL-EVAL-FD1-STATE S-APPROX-IMPLIES-B-APPROX
           FOURP-IMPLIES-S-APPROX-IS-B-APPROX FOURP-F-BUF
           FOURP-F-IF)
   (EXPAND (V-APPROX A1 A2) (V-APPROX (CDR A1) (CDR A2)))))
```

The macro `DISABLE-ALL` disables all of its arguments. The macro `REVERT-STATE` is intended to make the set of enabled rules be the same as those in existence just after the indicated event. In particular, the form `(REVERT-STATE BVP-REV1)` reverts to the state just after the lemma `BVP-REV1` in "approx.events".

See Section 14.67 for the event file "approx.events".

Chapter 12

ADDITIONAL PROPERTIES OF THE CHIP

In this chapter we conclude our proofs about the FM9001 netlist by showing that the chip's reset sequence has the desired effect and that the netlist is well-formed.

12.1 FINAL-RESET

The theorem `XS-SUFFICE-FOR-RESET-CHIP-LEMMA-INSTANCE` states that if the FM9001 is run starting in a completely unknown state, then after nineteen clock cycles after the reset input is disabled, the internal state of the FM9001 has been set to known values and is ready to execute user instructions. This reset process does not depend upon any internal state value, but does require that the reset line be asserted at the beginning of the reset sequence. One can check with simulation on any specific initial state that after the reset sequence that the FM9001 internal state is equal to `(FINAL-STATE)`.

The last part of this file contains the most general statements concerning the correctness of the FM9001 design. The final lemma `CHIP-SYSTEM=FM9001--INTERPRETER$AFTER-RESET` is the similar to the lemma named `CHIP-SYSTEM=-FM9001-INTERPRETER` in the file "proofs.events", except that it is specialized to the case where the initial state is made up of the chip state after reset (i.e., `(INITIALIZED-MACHINE-STATE)`) together with an appropriate machine memory. Thus, the hypothesis `(FM9001-STATE-STRUCTURE STATE)` has been omitted and the rather elaborate hypothesis `(MACROCYCLE-INVARIANT STATE)` has been replaced by the much weaker hypothesis `(MEMORY-OKP 32 32 MEMORY)`. We can do this because `(INITIALIZED-MACHINE-STATE)` satisfies the processor state portions

of these two hypotheses.

See Section 14.68 for the event file "final-reset.events".

12.2 WELL-FORMED-FM9001

The LSI logic tools require that certain syntactic conditions be met on the netlist, as well as the conditions we impose on our HDL; see Section 5.4 for a description of `TOP-LEVEL-PREDICATE`. The three `PROVE-LEMMA` events in this file show that all of these requirements are met.

See Section 14.69 for the event file "well-formed-fm9001.events".

Chapter 13

ALU INTERPRETATION LEMMAS

In this chapter we demonstrate the correctness of the results produced by the ALU and prove the correctness of the values stored in the flag registers. Looking back at Figure 1.1, we show that the "Integer Interpretation" and "Natural Number Interpretation" are equivalent to the the "Boolean Interpretation." We recommend that the reader, when interested in the ALU interpretations, skip reading the file "alu-interpretation.events" in favor of the file "more-alu-interpretation.events".

13.1 MATH-ENABLE

This file enables appropriate arithmetic lemmas after "winding back" to an appropriate state. See Section 2.5 for more information.

See Section 14.70 for the file "math-enable.events".

13.2 ALU-INTERPRETATION

The two main theorems in this file state that the ALU behaves as expected when its inputs are viewed as natural numbers or as integers (respectively). Let us take a look at the natural number version.

```
Theorem.  V-ALU-CORRECT-NAT
(implies (bv2p a b)
         (equal (v-alu c a b op)
                (v-alu-nat c a b op)))
```

The hypothesis `(BV2P A B)` says that `A` and `B` are bit vectors of the same length. Henceforth, let us imagine particular values of `C`, `A`, `B`, and `OP`, and assume that `(BV2P A B)` is true. Furthermore, in order to begin to understand the conclusion of the theorem above, let us see what it says in the special case that `OP` is the value `#v0010`, which happens to represent the add-with-carry operation.

In that case, and under our assumption of `(BV2P A B)`, the theorem immediately reduces to the following term when we open up the definitions of `V-ALU` and `V-ALU-NAT`, where again we take `OP` to equal `#v0010`.

```
(equal (cvzbv-v-adder c a b)
       (v-alu-nat-adder c a b))
```

The first argument of the `EQUAL` term above represents the value returned by the ALU when doing an add-with-carry operation, according to its low-level specification. The second argument of this term returns the value that the natural-number specification says the ALU ought to return.

If we open up the definitions of `CVZBV-V-ADDER` and `V-ALU-NAT-ADDER`, then the equality displayed above reduces to the following term.

```
(equal (cvzbv (v-adder-carry-out c a b)
              (v-adder-overflowp c a b)
              (v-adder-output    c a b))
       (cvzbv (v-alu-nat-adder-carry-out c a b)
              (v-adder-overflowp         c a b)
              (v-alu-nat-adder-output    c a b)))
```

It follows easily from the equality above and the definition of `CVZBV` that the following two equalities hold.

```
(equal (v-adder-carry-out c a b)
       (v-alu-nat-adder-carry-out c a b))

(equal (v-adder-output c a b)
       (v-alu-nat-adder-output c a b))
```

Let us focus further on the second of these equalities, as the first one is analogous (it is for the carry bit rather than for the bit-vector result). This equality supports our use of the term "interpretation lemma," as it relates a specification made at the bit level to one made using natural number operations. In particular, the function `V-ADDER-OUTPUT` returns the bit-level specification of the add-with-carry operation's bit-vector result, while the function `V-ALU-NAT-ADDER-OUTPUT` is

specified using natural number operations. Let us look at these two functions in turn.

The function `V-ADDER` is a bit-level specification of the bit-vector returned by the ALU's adder, and the function `V-ADDER-OUTPUT` is the result of stripping the high-order (carry) bit from that result. These definitions, the first of which happens to be recursive, are as follows.

```
Definition.
(v-adder c a b)
 =
(if (nlistp a)
    (cons (boolfix c) nil)
  (cons (b-xor3 c (car a) (car b))
        (v-adder (b-or (b-and (car a) (car b))
                       (b-or (b-and (car a) c)
                             (b-and (car b) c)))
                 (cdr a)
                 (cdr b))))

Definition.
(v-adder-output c a b)
 =
(firstn (length a) (v-adder c a b))
```

On the other hand, the function `V-ALU-NAT-ADDER-OUTPUT` is written using natural number operations. It specifies what the ALU's add-with-carry operation does when the inputs are viewed as bit-vector representations of natural numbers. Informally: the inputs `C`, `A`, and `B` are first converted to natural numbers, then added together, and finally, the result is converted back to a bit vector of the appropriate length.

```
Definition.
(v-alu-nat-adder-output c a b)
 =
(nat-to-v (remainder (plus (b-to-nat c)
                           (v-to-nat a)
                           (v-to-nat b))
                     (exp 2 (length a)))
          (length a))
```

For the natural number case, we do not prove anything about the overflow bit. We do prove properties about overflow when considering the integer interpretation of the ALU operations. Let us conclude this discussion by noting that

the integer interpretation theorem `V-ALU-CORRECT-INT` is similar to the theorem `V-ALU-CORRECT-NAT`. Bit vectors are viewed there as representing integers by the usual twos-complement scheme.

See Section 14.71 for the event file "alu-interpretation.events".

13.3 FLAG-INTERPRETATION

In this file we prove a number of lemmas about the `STORE-RESULTP` interpretations of the overflow, carry, zero, and negative bits flags, one for each particular kind of ALU operation when meaningful. In other words, assuming that the current instruction performs some operation, these lemmas tell how subsequent instructions would interpret the flag values computed in earlier instructions.

See Section 14.72 for the event file "flag-interpretation.events".

13.4 MORE-ALU-INTERPRETATION

The principal events of this file are the lemmas `BV-V-ALU-AS-NATURAL` and `BV-V-ALU-AS-INTEGER`. The lemmas in this file simply restate what was proved in the file "alu-interpretation.events" in an easily readable way.

See Section 14.73 for the event file "more-alu-interpretation.events".

Chapter 14

LIST OF FILES

In this chapter we present all of the source files used to define the FM9001 and check its correctness with Nqthm. Each file is given as a separate section starting on a separate page. The files are given in the order processed during an Nqthm run. Simply loading the second file, "sysdef.lisp", causes all the remaining files to be processed. The first file contains the public distribution license.

(in-package "USER")

;;;++++++++++++++++++++++++++++++++++++++++++++++++++++++++++++++++++++++++++++++
;;;
;;;    VECTOR-MODULE name (occ-name outputs type inputs) specs &key enable
;;;
;;;++++++++++++++++++++++++++++++++++++++++++++++++++++++++++++++++++++++++++++++
;;;
;;;    VECTOR-MODULE creates simple, linear, n-bit module generators.
;;;
;;;   Arguments:
;;;
;;;     name -- The generator will be (<name>* n)
;;;
;;;     (occ-name outputs type inputs) --  A schematic representation of the
;;;     occurrences.  The body of the generator will contain occurrences of the
;;;     form:
;;;           (<occ-name>_n
;;;            (<output_0>_n ... <output_k>_n)
;;;            type
;;;            (<input_0>_n ... <input_k>_n))
;;;
;;;     specs -- A list of specifications for the output vectors, written in
;;;     terms of the inputs.
;;;
;;;     enable -- A list of events to be enabled.
;;;
;;;   Example: (vector-module v-buf (g (y) b-buf (a)) ((v-threefix a))
;;;                           :enable (f-buf))
;;;
;;;   More examples in "vector-module.events".

;;;
;;;    *STATE-TABLE*
;;;
;;;    *STATE-TABLE*, along with *CONTROL-TEMPLATE*, forms a Common LISP
;;;    encoding of the FM9001 state machine. Each entry contains the
;;;    state name, an expression for the next state, and a set of control line
;;;    assignments.  If the name of a control line is given, then the
;;;    non-default Boolean value is selected.  A pair, (<control-line> <value>)
;;;    assigns that value to the control line in that state.
;;;
;;;****************************************************************************

;;;
;;;    SINGLE STEP SIMULATIONS
;;;
;;;  The STEP-FM9001 macro creates a lemma that describes the new state
;;;  computed by a single step of the low-level machine from the given initial
;;;  state.  This procedure is complicated by the fact that the next state
;;;  depends on the state of the memory.  Rather than produce a single lemma
;;;  that captures the behavior for all possible memory states, we create
;;;  separate lemmas only for those processor-state/memory-state configurations
;;;  that are possible during normal instruction execution.  This is important
;;;  because if the memory protocol is not followed, then unknown values may be
;;;  loaded into the processor registers.  What we are doing here is creating
;;;  a state-by-state, almost-Boolean specification of the low-level machine.
;;;  So we obviously we want to insure that the processor state remains
;;;  Boolean.
;;;
;;;  STEP-FM9001 is used in "expand-fm9001.events".
;;;

;;;
;;;    Chunk Simulations
;;;
;;;  SIM-FM9001 is a macro that creates lemmas that describe the operation of
;;;  the machine for multiple clock cycles.  We create a multi-state simulation
;;;  for each non-branching segment of the state diagrams.  For this purpose,
;;;  we consider the states that wait for memory as "non-branching".  Notice
;;;  that some of the "multi-state" lemmas only include a single state.
;;;
;;;  SIM-FM9001 is used in "expand-fm9001.events"
;;;
;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;
```

;;;
;;;    TRANSLATE.LISP
;;;
;;;    A DUAL-EVAL HDL to LSI Logic NDL translator.
;;;
;;;~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~

(in-package "USER")

;;;
;;; The netlist arg to functions PRINT-NDL-FORM-TO-FILE and PRINT-NDL-FORM
;;; should look like (LISP-NETLIST <netlist>), where <netlist> is a well-formed
;;; netlist.  Recall that LISP-NETLIST changes (INDEX name num) names to
;;; 'name_num names. Make the netlist arg in r-loop by doing
;;;
;;;     (SETQ var (LISP-NETLIST <netlist>))
;;;
;;; Outside of r-loop, the netlist arg will be
;;;
;;;     (CDR (ASSOC 'var R-ALIST))
;;;
;;;
;;; For example, to translate a the entire FM9001 netlist stored in Nqthm as
;;; (CHIP$NETLIST), do the following:
;;;
;;; > (r-loop)
;;; *(SETQ NETLIST (LISP-NETLIST (CHIP$NETLIST)))
;;; ... <r-loop prints the netlist> ..
;;; *OK
;;; > (PRINT-NDL-FORM-TO-FILE (CDR (ASSOC 'NETLIST R-ALIST)) "chip.ndl")
;;;
;;; The translated netlist will be written to "chip.ndl"
;;;
;;; This process defines certain modules that are assumed to be primitives of
;;; our netlist language.

;;;  PRINT-NDL-FORM-TO-FILE netlist file-name
;;;
;;;  This is the top-level call to the translator.  The NDL form of the NETLIST
;;;  will be written to file FILE-NAME.

        *mods-alist*)
    nil))

;; The purpose of this utility is to allow one to take a completed
;; proof effort using (pc-)nqthm and "purify" it a sense I'll now
;; describe.

;; Nqthm users commonly write macros that generate events.  Also,
;; nqthm users at CLI tend to use the "saved_pc-nqthm" core image,
;; which includes local modifications to pc-nqthm.  In some cases
;; there's really no use of pc-nqthm at all beyond what's in nqthm,
;; except perhaps for theories; hence I've also created a file
;; "deftheory.lisp" that contains the disabledp patch and deftheory,
;; but only these.  (Probably I could have left out the disabledp
;; patch, but I didn't want to think about the ramifications that
;; would have for deftheory.)

;; At any rate, once one chooses a core image that corresponds to
;; one of the the publicly released systems -- i.e. either nqthm
;; or pure-pc-nqthm -- one might like to specify some additional
;; forms to execute (perhaps to load files like "deftheory" or
;; "fast-clausifier") and also a library to replay.  The effect should
;; be as illustrated below.

;; 1. The library is used to create an events file.

;; 2. Nqthm or pure-pc-nqthm is started up, with the indicated forms
;;    executed.

;; 3. A proveall is run using the events file created in the first step.

;; A sample transcript occurs at the end of the file.

;; Modifications by B. Brock, July 1993.
;;
;; This now simply creates a file of events, NOT a PROVEALL.
;;
;; The FM9001 proof contains several occurrences of COMPILE-UNCOMPILED-DEFNS,
;; of which there is no trace in the final chronology.  I defined a new macro,
;; COMPILE-UNCOMPILED-DEFNS*, and modified Matt's LIBRARY-TO-EVENTS, to handle
;; this problem.  This macro introduces a new Nqthm function called
;; COMPILE-UNCOMPILED-DEFNS, whose ENABLE events are recognized and used as a
;; tag to insert calls to COMPILE-UNCOMPILED-DEFNS.
;;
;; We also automatically add the (SETQ REDUCE-TERM-CLOCK 2000) form.
```

```

Sample transcript.  It assumes that we used pc-nqthm on the following
events to create library "foo", i.e. "foo.lib" and "foo.lisp" in that
same directory.

(do-events '(

(prove-lemma times-comm (rewrite)
  (equal (times x z) (times z x)))

(defn blob (x)
  (let ((y (plus x x)))
    (times y 3)))

(prove-lemma times-add1 (rewrite)
  (equal (times (add1 x) y)
         (plus y (times x y))))
```

```
(prove-lemma blob-val nil
  (equal (blob x)
         (cond ((zerop x) 0)
               (t (times 6 x)))))
))

.... and, here's what we do to create a pure nqthm events file
"foo-replay.events":

% pc-nqthm

;; NATURALS Theory

;; Created by Bill Bevier 1988 (see CLI internal note 057)

;; Modifications by Bill Bevier and Matt Wilding (9/89) including
;; adding some new metalemmas for times, reorganizing the theories,
;; removing some extraneous lemmas, and removing dependence upon
;; other theories (by adding the pertinent lemmas).

;; This script requires the bags theory

;; This script sets up a theory for the NATURALS with the following subtheories
;; ADDITION
;; MULTIPLICATION
;; REMAINDER
;; QUOTIENT
;; EXPONENTIATION
;; LOGS
;; GCDS

;; The theories of EXPONENTIATION, LOGS, and GCDS still need a lot of work

```
;;;  Copyright (C) 1990-1994 Computational Logic, Inc.  All Rights
;;;  Reserved.  See the file LICENSE in this directory for the
;;;  complete license agreement.

;; By Matt Kaufmann, modified from earlier integer library of Bill
;; Bevier and Matt Wilding.  A few functions (even ILESSP) have
;; been changed, but I expect the functionality of this library to
;; include all the functionality of the old one in most or even all
;; cases.

;; Modified from /local/src/nqthm-libs/integers.events to get ILEQ
;; expressed in terms of ILESSP and IDIFFERENCE in terms of INEG and
;; IPLUS.  There are other changes too.  The highlights are the new
;; metalemmas.

;; I'm going to leave the eval$ rules on that are proved here, and
;; leave eval$ off.

;; My intention is that this library be used in a mode in which ILEQ
;; and IDIFFERENCE are left enabled.  Otherwise, the aforementioned
;; meta lemmas may not be very useful, and also a number of additional
;; replacement rules may be needed.

;; There are three theories created by this library.  INTEGER-DEFNS is
;; a list of definitions of all integer functions (not including the
;; cancellation metafunctions and their auxiliaries, though), except
;; that ILEQ and IDIFFERENCE have been omitted.  This is a useful
;; theory for an ENABLE-THEORY hint when one simply wants to blast all
;; integer functions open, and it's also useful if one wants to close
;; them down with a DISABLE-THEORY hint (perhaps to go with an
;; (ENABLE-THEORY T) hint).  Second, ALL-INTEGER-DEFNS is the same as
;; INTEGER-DEFNS except that ILEQ and IDIFFERENCE are included in this
;; one.  Finally, INTEGERS is a list of all events to be "exported as
;; enabled" from this file when working in a mode where everything not
;; enabled by an ENABLE-THEORY hint is to be disabled.  Notice that
;; some rewrite rules have been included that might appear to be
;; unnecessary in light of the metalemmas; that's because metalemmas
;; only work on tame terms.  However, there's no guarantee that the
;; rewrite rules alone will prove very useful (on non-tame terms).
;; Also notice that INTEGER-DEFNS is disjoint from INTEGERS, since we
;; expect the basic definitions (other than ILEQ and IDIFFERENCE) to
;; remain disabled.

;; It's easy to see what I have and haven't placed in INTEGERS, since
;; I'll simply comment out the event names that I want to exclude (see
;; end of this file).

;; One might wish to consider changing (fix-int (minus ...)) in some
;; of the definitions below to (ineg ...).

;; The following meta rules are in this library.
;; (A little documentation added by Matt Wilding July 90)
```

```
;;
;; CORRECTNESS-OF-CANCEL-INEG
;;  cancel the first argument of an iplus term with a member of the second
;;  argument.
;;
;;  ex:  (iplus (ineg y) (iplus (ineg x) (iplus y z)))
;;     -->
;;       (iplus (ineg x) (fix-int z))
;;
;; CORRECTNESS-OF-CANCEL-IPLUS
;;  cancel the sides of an equality of iplus sums
;;
;;  ex:  (equal (iplus x (iplus y z)) (iplus a (iplus z x)))
;;     -->
;;       (equal (fix-int y) (fix-int a))
;;
;; CORRECTNESS-OF-CANCEL-IPLUS-ILESSP
;;  cancel the sides of an ilessp inequality of sums
;;
;;  ex:  (ilessp (iplus x (iplus y z)) (iplus a (iplus z x)))
;;     -->
;;       (ilessp y a)
;;
;; CORRECTNESS-OF-CANCEL-ITIMES
;;  cancel the sides of an equality of itimes products
;;
;;  ex: (equal (itimes x (itimes y z)) (itimes a (itimes z x)))
;;     -->
;;      (if (equal (itimes x z) '0)
;;        t
;;        (equal (fix-int y) (fix-int a)))
;;
;; CORRECTNESS-OF-CANCEL-ITIMES-ILESSP
;;  cancel the sides of an inequality of itimes products
;;
;;  ex: (ilessp (itimes x (itimes y z)) (itimes a (itimes z x)))
;;     -->
;;      (if (ilessp (itimes x z) '0)
;;         (ilessp a y)

; ------------------------------------------------------------------------
; Cancel IPLUS
; ------------------------------------------------------------------------

;; All I do here is cancel like terms from both sides.  The problem of
;; handling INEG cancellation IS handled completely separately above.
;; That hasn't always been the case -- in my first try I attempted to
;; integrate the operations.  But now I see that for things like
;; (equal z (iplus x (iplus y (ineg x)))) the integrated approach will
;; fail.  Also, thanks to Matt Wilding, for pointing out that the
;; "four squares" example that Bill Pase sent me ran faster with the
;; newer approach (on his previously-implemented version for the
;; rationals).

; Cancel IPLUS from ILESSP
; ------------------------------------------------------------------------

;; This is similar to the cancellation of IPLUS terms from equalities,
;; handled above, and uses many of the same lemmas.  A small but definite
;; difference however is that for ILESSP we don't have to fix integers.

;; By luck we have that iplus-tree-rec is appropriate here, since
;; the lemma eval$-iplus-tree-rec shows that it (accidentally) behaves
;; properly on the empty list.

; It turns out that in computer arithmetic, notions of division other than that
; given by the division theorem are used. Two in particular, called
; "truncate towards negative infinity" and "truncate towards zero" are common.
; We present their definitions here.

; Division Theorem (truncate towards negative infinity variant):
;
; For all integers i,j, j not 0, there exist unique integers q and r
; which satisfy
;                i = jq + r,  0 <= r <  j  (j > 0)
;                             j <  r <= 0  (j < 0)
;
; In this version the integer quotient of two integers is the integer floor
; of the real quotient of the integers. The remainder has the sign of the
; divisor. The functions IDIV and IMOD are intended to compute q and r.
; Therefore, to be satisfied that we have the right definitions, we must
; prove the above theorem.

; ---------- Meta lemma for itimes cancellation

;; I tried to adapt this somewhat from corresponding meta lemmas in
;; naturals library, but it seemed to get hairy.  So instead I'll try
;; to parallel the development I gave for IPLUS.  I'll be lazier here
;; about efficiency, so I'll use a completely analogous definition of
;; itimes-tree.  Notice that I've avoided the IZEROP-TREE approach
;; from the naturals version, in that I simply create the appropriate
;; common fringe into a product and say that this product is non-zero
;; when dividing both sides by it.  It can then be up to the user
;; whether or not to enable the (meta or rewrite) rule that says that
;; izerop of a product reduces to the disjunction of izerop of the
;; factors.

#| The function below has no AND or OR, for efficiency
```

;;;;;; ***** EXTRA META STUFF ***** ;;;;;;

;; The next goal is to improve itimes cancellation so that it looks
;; for common factors, and hence works on equations like
;;    x*y + x = x*z
;; and, for that matter,
;; a*x + -b*x = 0.

;; Rather than changing the existing cancel-itimes function, I'll
;; leave that one but disable its metalemma at the end.  Then if the
;; new version, which I'll call cancel-itimes-factors, is found to be
;; too slow, one can always disable its metalemma and re-enable the
;; metalemma for cancel-itimes.

;; Notice, by the way, that the existing cancel-itimes function is
;; useless for something like the following, since there's no special
;; treatment for INEG.  I'll remedy that in this version.

;;;~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~
;;;
;;;    MEMORY.EVENTS
;;;
;;;~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~
;;;
;;;  This file defines a tree-based formalization of memory.  This
;;;  tree-based memory offers advantages over a linear-list formalization.
;;;  Specifically, reading and writing the memory take O(log n) time and
;;;  CONS operations respectively, where n is the number of words in the
;;;  memory.  Also, we are able to "stub-out", or leave unspecified, large
;;;  sections of the memory.
;;;
;;;  Memory is modeled as a CONS tree, where the leaves of the tree are
;;;  instances of one of three special shells: the shell constructor ROM
;;;  tags read-only locations of the memory, while the shell constructor
;;;  RAM tags read-write locations and STUB represents ``unimplemented''
;;;  portions.  Each instance of the memory shells includes a value, which
;;;  is returned when that memory location is read.  RAM cells may be
;;;  overwritten, but writing to a ROM or STUB cell does not change the
;;;  memory.  ROM cells may only appear at the leaves of the tree, wheras
;;;  STUB cells may appear anywhere.  Although our basic definitions do not
;;;  restrict the types of data stored in memory, we assume throughout the
;;;  specification of the FM9001 (and enforce) the restriction
;;;  that only bit-vectors are stored in memory.
;;;
;;;  The bit-vector that specifies the address is used in an obvious way to
;;;  search the memory tree for the addressed location.  Note, however,
;;;  that the address is reversed prior to the search.  This allows for
;;;  more compact storage for sequences of data.  If the address were not
;;;  reversed, then the memory trees would be subject to branching near the
;;;  root of the tree.  With reversed addresses, the branching is localized
;;;  near the leaves. This is an especially important consideration for the
;;;  main memory of the FM9001.  There, each path through the memory tree
;;;  to a leaf cell is constructed from 32 CONS cells.

;;;~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~
;;;
;;;    DUAL-PORT-RAM.EVENTS
;;;
;;;~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~
;;;
;;;  This file contains a model of a dual-port ram:
;;;
;;;  (DUAL-PORT-RAM-VALUE bits address-lines args state)
;;;
;;;  returns the RAM output, i.e., the contents of the memory addressed by the
;;;  read-adress port.
;;;
;;;  (DUAL-PORT-RAM-STATE bits address-lines args state)
;;;
;;;  updates the state of the RAM.
;;;
;;;  The ARGS are assumed to be structured as follows:
;;;
;;;  0..(ADDRESS-LINES - 1)               -- A (read port) address.
;;;  ADDRESS-LINES..(2*ADDRESS-LINES - 1) -- B (write port) address.
;;;  (2*ADDRESS-LINES)                    -- WEN, active low.
;;;  remainder                            -- DATA lines.
;;;
;;;    WARNING -- This is a sequential model of what is essentially a
;;; level-sensitive device.  Note that this state-holding device has no clock
;;; input.  Spikes on WEN, or changes on B-ADDRESS while WEN is active may
;;; cause unanticipated changes in the memory state of the real device.
;;;
;;;    The dual-port RAM used in the register file of the FM9001 is surrounded
;;;  by sequential logic that ensures that setup and hold constraints are met.
;;;  See the file "regfile.events".

;;;~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~
;;;
;;;    FM9001-MEMORY.EVENTS
;;;
;;;~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~

;;;   This is a model of a generic memory for the FM9001.  Besides the
;;;   state component, the memory takes as input a STROBE (active low), a
;;;   read/write line (low to write), and address and data lines.
;;;
;;;   The state component consists of the memory contents, a memory control
;;;   state (see below), a "clock" (see below), a "count" used for DTACK
;;;   scheduling, a flag indicating that DTACK has been asserted, the last
;;;   value of RW- and the last address and data inputs.
;;;
;;;   Address lines, and data lines on a write, must be stable for one cycle
;;;   before the strobe is activated, and one cycle after the strobe is
;;;   released.  On a write, the same setup/hold constraints also must be met
;;;   by the low pulse on RW-.
;;;
;;;   Memory control states:
;;;
;;;   0 -- The quiet state.
;;;   1 -- Read wait.
;;;   2 -- Write wait.
;;;   x -- Error.
;;;
;;;   The "clock" is an oracle that specifies the wait for DTACK.  Whenever the
;;;   STROBE is activated, then (CAR clock) is the number of memory delays for
;;;   this memory operation, and the new "clock" becomes (CDR clock).  For
;;;   simulation purposes we normally set this to 0 to provide minimum delays
;;;   since both the CAR and CDR of 0 are 0.
```

;;;~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~
;;;
;;;    TREE-NUMBER.EVENTS
;;;
;;;    (TREE-NUMBER tree) returns a unique (we think) number for each
;;;    equivalence class of trees with the same CONS structure.  We use this
;;;    to give unique, numerical indices to modules created by tree-based
;;;    module generators.  We never proved that TREE-NUMBER yields a unique
;;;    encoding, but our netlist predicates would fail if it were ever the case
;;;    that non-unique encodings were produced.
;;;
;;;~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~
;;;
;;;    This definition of TREE-NUMBER has the property that a balanced tree
;;;    with N leaves has (TREE-NUMBER TREE) = N.   In the binary encoding of
;;;    the tree, each "full" level (whether full of CONS cells or leaves) is
;;;    encoded as T.  Partially empty levels are encoded by F, followed by a
;;;    bit string that encodes with T and F those locations that are filled and
;;;    empty respectively.

;;;    PREDICATE-SIMPLE.EVENTS
;;;
;;;~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~

;;;~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~
;;;
;;;  Syntax Requirements for Hardware Description Language
;;;
;;;  The predicate TOP-LEVEL-PREDICATE-SIMPLE is a simpler version
;;;  of the circuit predicate in file "predicate.events".  These
;;;  predicates only return a symbol indicating what main property
;;;  was violated.  The circuit recognizer predicates in file
;;;  "predicate.events" return more useful information, but the
;;;  functions there are much more complex.
;;;
;;;  We don't use these circuit predicates during our proofs; however,
;;;  once we have a netlist we check its well-formedness using these
;;;  predicates.

;;;
;;;
;;;    PREDICATE.EVENTS
;;;
;;;
;;;~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~

;;;  Here we attempt to define a predicate that recognizes well-formed
;;;  circuits.  Syntactically, this is straightforward; however, for
;;;  bi-directional busses the ordering of primitives may result in
;;;  different evaluations.  There is also the concern about
;;;  combinational circularities in our circuit descriptions.
;;;  Hopefully, the predicates below do not admit such circuits.

;;;  The name of the predicate is TOP-LEVEL-PREDICATE.  It has one
;;;  parameter, a netlist (the normal HDL circuit description).

;;;  A second predicate LSI-TOP-LEVEL-PREDICATE has additional checks
;;;  for LSI Logic's requirements.  It has three parameters:
;;;    netlist - a netlist, in which all names are litatoms
;;;    token-size - maximum allowed name length (should be 64)
;;;    max-hierarchical-name-length - (should be 255)
;;;
;;;  The netlist predicates work in two stages.  First, they check the
;;;  netlist for syntax errors (functions NETLIST-SYNTAX-OK,
;;;  LSI-NETLIST-SYNTAX-OK).  Then, they check for other errors by
;;;  attempting to construct a database of netlist properties
;;;  (function NETLIST-PROPERTIES).

;;;  Also included is function NETLIST-DATABASE, which constructs a
;;;  database of netlist properties similar to the primitive database.
;;;  The netlist database does not contain LSI-NAME, NEW-STATES, and
;;;  RESULTS properties, but it does contain all the other primitive
;;;  properties.  NETLIST-DATABASE assumes there are no syntax errors
;;;  in the netlist.

;;;  Correct results from all the functions mentioned above depend on
;;;  a well-formed primitive database.  This is determined by function
;;;  PRIMP-DATABASE-PREDICATE (no parameters).

;;;  Test data for the predicates is in file predicate.tests.

;;;~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~
;;;
;;;    Syntax Requirements for Hardware Description Language
;;;
```

```
;;;~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~

;;; The netlist syntax is:
;;;
;;;   <netlist> ::= ( <module>* )
;;;
;;;   <module> ::= ( <module name> <module inputs> <module outputs>
;;;                  <module occurrences> <module state names>
;;;                  [ <annotation> ] )
;;;
;;;   <module name> ::= <name>
;;;
;;;   <module inputs> ::= ( <name>* )
;;;
;;;   <module outputs> ::= ( <name>* )
;;;
;;;   <module occurrences> ::= ( <occurrence>+ )
;;;
;;;   <module state names> ::= <name> | ( <name> <name>+ )
;;;
;;;   <annotation> ::= ( ( <key> . <value> )* )
;;;
;;;   <occurrence> ::= ( <occurrence name> <occurrence outputs>
;;;                      <occurrence function> <occurrence inputs>
;;;                      [ <annotation> ] )
;;;
;;;   <occurrence name> ::= <name>
;;;
;;;   <occurrence outputs> ::= ( <name>* )
;;;
;;;   <occurrence function> ::= <name>
;;;
;;;   <occurrence inputs> ::= ( <name>* )
;;;
;;;   <name> ::= <simple name> | <indexed name>
;;;
;;;   <simple name> is a litatom
;;;
;;;   <indexed name> is a shell object, constructed by
;;;                  (index <simple name> <number>),
;;;                  where <number> is a numberp
;;;
;;;   <key> is unrestricted
;;;
;;;   <value> is unrestricted
;;;

;;;
;;; Additional syntax requirements are:
;;;
;;;   1.  There are no duplicate <module name>'s in the <netlist>, and no
;;;       <module name> is the same as a primitive name.
;;;
;;;   2.  There are no duplicate signal names within a <module> except for
```

```
;;;       IO-signals (intersection of <module inputs> and <module outputs>).
;;;       The signals of a module are <module inputs> and <occurrence outputs>
;;;       from all the <module occurrences>.
;;;
;;;   3.  All <module outputs> are generated once and only once as
;;;       <occurrence outputs> within the <module>.
;;;
;;;   4.  All <occurrence inputs> within a <module> are signals of the module.
;;;
;;;   5.  <Module state names> are a subset of the module's
;;;       <occurrence name>'s.
;;;
;;;   6.  There are no duplicate <occurrence name>'s within a module.
;;;
;;;   7.  Every <occurrence function> names either a primitive or a <module>
;;;       defined in the <netlist> before the <module> where the
;;;       <occurrence function> appears.
;;;
;;;   8.  Numbers of <occurrence inputs> and <occurrence outputs> are the same
;;;       as the numbers of inputs and outputs required by the definition of
;;;       the module or the description of the primitive named by the
;;;       <occurrence function>.

;;;~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~
;;;
;;;    Syntax Requirements for LSI Logic's Network Description Language
;;;
;;;~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~

;;;  LSI Logic's Network Description Language (NDL) has the following
;;;  additional syntax requirements:
;;;
;;;  1.  A <name> is a standard litatom beginning with an upper case letter
;;;      and containing only upper case letters, digits, hyphens (-), and
;;;      underscores (_).  A <name> can contain at most 64 characters
;;;      (token-size).  No name can be an NDL keyword.
;;;
;;;  2.  LSI Logic uses hierarchical names to provide a unique name for each
;;;      signal in the circuit.  The hierarchical name is composed by appending
;;;      /<occurrence name> for each occurrence in an instance tree until a
;;;      primitive is reached; at that point /<name> is appended, where <name>
;;;      is the name of a signal in the occurrence that is an instance of the
;;;      primitive.  No hierarchical name can contain more than 255 characters
;;;      (hierarchical-size).
;;;
;;;  3.  No signal name (module input or occurrence output, including module
;;;      outputs) can be the same as an occurrence name except that if an
;;;      occurrence has only one output, then the output name can be the same
;;;      as the name of that occurrence.
;;;
;;;  4.  No signal name or occurrence name in a module can be the same as the
;;;      name of any function used within the module.  If the function
;;;      is a primitive, LSI Logic's name for it is the one that must
;;;      not be used as a signal or occurrence name.

;;;~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~
;;;
;;;    Module Input/Output Types
;;;
;;;~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~

;;;  Below are functions that check the types of module inputs and outputs.
;;;
;;;  Known input types:
;;;    (BOOLP CLK FREE LEVEL PARAMETRIC TRI-STATE TTL TTL-TRI-STATE)
;;;
;;;  Known output types:
;;;    ((<an input name>)
;;;     BOOLP CLK LEVEL PARAMETRIC TRI-STATE TTL TTL-TRI-STATE)

;;;  Contradictory type requirements give an error.  IO signals must
;;;  have tri-state output types and either tri-state or free input
;;;  types.  T-wire inputs must have tri-state input and output types.
;;;  Otherwise, the output type of a signal is required to be a
;;;  subtype of its input type.

;;;                       | ( UNKNOWN ) ;; There was an error.
;;;                       | ( OR <module delay> <module delay>+ )
;;;                       | ( ( <slope,LH> <mintercept,LH> )
;;;                           ( <slope,HL> <mintercept,HL> )
;;;                           <delay dependency>* )
;;;
;;;    <mintercept> ::= <number> | ( RANGE <number> <number> )
;;;
;;;    <delay dependency> ::=   <input or output name>
;;;                           | ( UNKNOWN ) ;; There was an error.
;;;                           | ( OR <delay dependency> <delay dependency>+ )
;;;                           | ( RANGE <number> <number> <delay dependency>* )
;;;                           | <number>
;;;
;;;  Occurrence data delay:
;;;    <occurrence data delay> ::= <module delay>
;;;
;;;  IO-signal output is represented as ( IO-OUT <signal name> ).

;;;  In the normal case, delay to produce a signal S is given by
;;;
;;;     ( ( <slope,LH> (range min-LH-intercept max-LH-intercept ) )
;;;       ( <slope,HL> (range min-HL-intercept max-HL-intercept ) )
;;;       <delay dependency>* )
;;;
;;;  where the <delay dependency>'s represent the amount of time
;;;  required to produce the inputs signal S depends on.  The <delay
;;;  dependency>'s normally have the form
```

```
;;;
;;;      (range min-input-delay max-input-delay <delay dependency>*)
;;;
;;;  When all <delay dependency>'s are completely determined, the
;;;  minimum and maximum amount of time to produce all the inputs is
;;;  added to the minimum and maximum intercept values of the S delay.
;;;
;;;  The problem with this approach is that many of the <delay
;;;  dependency>'s are not fully determined in a large netlist.  For
;;;  the CHIP-SYSTEM netlist, adding delays increased the size of the
;;;  database produced by NETLIST-DATABASE from about 500,000
;;;  characters to about 10,000,000 characters.
;;;
;;;  To reduce the volume of the delay representation, we introduce
;;;  the following approximation into the delay intercept and
;;;  dependency computations.
;;;
;;;     ((slope-LH (range LH-min LH-max))
;;;      (slope-HL (range HL-min HL-max))
;;;      (range min-in-1 max-in-1 <in-1-dep-1> <in-1-dep-2> ... <in-1-dep-m1>)
;;;      (range min-in-2 max-in-2 <in-2-dep-1> <in-2-dep-2> ... <in-2-dep-m2>)
;;;      ...
;;;      (range min-in-n max-in-n <in-n-dep-1> <in-n-dep-2> ... <in-n-dep-mn>)
;;;      <name-dep-1> <name-dep-2> ... <name-dep-n2>)
;;;  ~=
;;;    ((slope-LH (range (plus LH-min (max min-in-1 min-in-2 ... min-in-n))
;;;                      (plus LH-max (max max-in-1 max-in-2 ... max-in-n))))
;;;     (slope-HL (range (plus HL-min (max min-in-1 min-in-2 ... min-in-n))
;;;                      (plus HL-max (max max-in-1 max-in-2 ... max-in-n))))
;;;     <in-1-dep-1> <in-1-dep-2> ... <in-1-dep-m1>
;;;     <in-2-dep-1> <in-2-dep-2> ... <in-2-dep-m2>
;;;     ...
;;;     <in-n-dep-1> <in-n-dep-2> ... <in-n-dep-mn>
;;;     <name-dep-1> <name-dep-2> ... <name-dep-n2>)
;;;
;;;  The approximation tends to make both the minimum and the maximum
;;;  intercept values higher than they should be.  With the
;;;  approximation, the CHIP-SYSTEM database has 922,130 characters.

;;;
;;;   UNBOUND.EVENTS
;;;
;;;   For doing proofs of recursive module generators, it is often necessary to
;;;   know that a signal name is "unbound", i.e., does not appear further in
;;;   the generated body.  By a "body" we mean an occurrence body, and by
;;;   "bound" we mean assigned a value in the ALIST created by DUAL-EVAL with
;;;   flag 1.  This concept is eloquently summed up in the final two lemmas of
;;;   this file.
;;;
;;;~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~

;;;
;;;  FAST-ZERO
;;;
;;;  A zero detector optimized for quick detection of the last 2 bits of the
;;;  input vector.  It should save a few nanoseconds in the FM9001.
;;;
;;;  LSI Logic timing analysis of the final design showed that this "fast"
;;;  zero-detector was about the same as simple, fully-balanced zero-detectors
;;;  defined in "t-or-nor.events".
;;;
;;;++++++++++++++++++++++++++++++++++++++++++++++++++++++++++++++++++++++++++++++

;;;~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~
;;;
;;;    TV-DEC-PASS.EVENTS
;;;
;;;   The output of the decrement/pass unit is either the input, or the input
;;;   decremented by 1.  This unit computes A - C, where A is the input vector,
;;;   and C is a 1-bit control signal representing 1 or 0.
;;;
;;;~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~

;;;  TV-DEC-PASS is a Boolean specification for a decrement/pass unit with a
;;;  carry-lookahead structure specified by the TREE input.  Carry-lookahead is
;;;  based on a single generate bit.  The CAR of the output vector is the
;;;  generate bit,  and the CDR of the output vector is A if C is high, else
;;;  A - 1.  Note that the parity of C is opposite from that specified above.

;;;   PRE-ALU.EVENTS
;;;
;;;   The ALU decoders, and CARRY-IN-HELP
;;;
;;;~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~

#|

  This table shows the settings of the mode, propagate, and generate lines for
each op-code that are computed by DECODE-MODE, DECODE-PROP, and DECODE-GEN
respectively.  Further, it shows carry-in, carry-out, and overflow requirements
that are implemented by CARRY-IN-HELP, CARRY-OUT-HELP, and OVERFLOW-HELP
respectively.   This table is valid assuming that the SWAP input to
DECODE-MODE and DECODE-GEN is true only when the op-code is either ALU-INC-OP
or ALU-DEC-OP.  (The SWAP input is normally F; it is set to T only in the cases
where the B operand is incremented or decremented.)  Also note that the control
logic must set the op-code to ALU-INC-OP whenever the ZERO flag is T.

;;;
;;;   CORE-ALU.EVENTS
;;;
;;;   CORE-ALU is the hardware implementation of the high-level specification
;;;   V-ALU.  In addition to the functions provided by V-ALU, CORE-ALU also can
;;;   be forced to 0, and includes INC B and DEC B operations for address
;;;   calculations.  Note that the control lines for the function generators
;;;   (MPG) are supplied by the control logic.
;;;
;;;   Since CORE-ALU is defined in terms of F$FAST-ZERO, only ALU sizes of >= 3
;;;   bits have the desired properties.
;;;
;;;~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~

   FM9001 -- a processor for a new decade.

   Instruction format:
                                                          { N/A  mode-a rn-a
                                                          {  3     2      4
unused op-code store-cc set-flags mode-b rn-b a-immediate |
  4       4       4        4        2      4        1     {    a-immediate
                                                          {         9

The A operand is a 10 bit field.  If the high order bit is set, the low order
9 bits are treated as a signed immediate.  Otherwise, the low order six bits of
the A operand are a mode/register pair identical to the B operand.
```

```
(Note:  We use "a" for "rn-a" and "b" for "rn-b" below.)

Interpretation of the OP-CODE.

 0000  b <- a             Move
 0001  b <- a + 1         Increment
 0010  b <- a + b + c     Add with carry
 0011  b <- b + a         Add
 0100  b <- 0 - a         Negation
 0101  b <- a - 1         Decrement
 0110  b <- b - a - c     Subtract with borrow
 0111  b <- b - a         Subtract
 1000  b <- a >> 1        Rotate right, shifted through carry
 1001  b <- a >> 1        Arithmetic shift right, top bit copied
 1010  b <- a >> 1        Logical shift right, top bit zero
 1011  b <- b XOR a       Exclusive or
 1100  b <- b | a         Or
 1101  b <- b & a         And
 1110  b <- ~a            Not
 1111  b <- a             Move

Interpretation of the STORE-CC field.

 0000  (~c)                          Carry clear
 0001  (c)                           Carry set

#|
   FM9001 -- a processor for a new decade.

   Instruction format:
                                                          { N/A  mode-a rn-a
                                                          {  3     2      4
unused op-code store-cc set-flags mode-b rn-b a-immediate |
  4       4       4        4        2      4        1     {    a-immediate
                                                          {         9

The A operand is a 10 bit field.  If the high order bit is set, the low order
9 bits are treated as a signed immediate.  Otherwise, the low order six bits of
the A operand are a mode/register pair identical to the B operand.
```

```
(Note:  We use "a" for "rn-a" and "b" for "rn-b" below.)

Interpretation of the OP-CODE.

 0000  b <- a             Move
 0001  b <- a + 1         Increment
 0010  b <- a + b + c     Add with carry
 0011  b <- b + a         Add
 0100  b <- 0 - a         Negation
 0101  b <- a - 1         Decrement
 0110  b <- b - a - c     Subtract with borrow
 0111  b <- b - a         Subtract
 1000  b <- a >> 1        Rotate right, shifted through carry
 1001  b <- a >> 1        Arithmetic shift right, top bit copied
 1010  b <- a >> 1        Logical shift right, top bit zero
 1011  b <- b XOR a       Exclusive or
 1100  b <- b | a         Or
 1101  b <- b & a         And
 1110  b <- ~a            Not
 1111  b <- a             Move

Interpretation of the STORE-CC field.

 0000  (~c)                          Carry clear
 0001  (c)                           Carry set
 0010  (~v)                          Overflow clear

;;;
;;;    FLAGS.EVENTS
;;;
;;;~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~

;;;  The FLAGS register is simply four, individually write-enabled, 1-bit
;;;  latches.  For simplicity the FLAGS register takes the entire 35-bit ALU
;;;  bus as an input, even though it only needs 4 of the bits, i.e., the C, V,
;;;  N, and Z.  Test input = TI.  Test output = C.

;;;~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~
;;;
;;;    PAD-VECTORS.EVENTS
;;;
;;;    Vector modules of I/O pads.
;;;
;;;~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~

;;;  It greatly simplifies the proofs at the CHIP level to package the pads
;;;  into the modules defined in this file.  However, LSI logic requires
;;;  every module to contain at least 1 "interior gate", i.e., a gate that is
;;;  not a pad.  Therefore, in some places we introduce redundant buffers.

;;;+++++++++++++++++++++++++++++++++++++++++++++++++++++++++++++++++++++++++++++
;;;
;;;    CHIP
;;;
;;;    The entire chip, with pads, as a module.
;;;
;;; INPUTS:
;;;
;;;  The system clock input is a special two-pad, clock-driver buffer.
;;;  The other inputs are ordinary TTL inputs.
;;;
;;;    CLK  -- The system clock
;;;
;;;    TI   -- Test input (Scan in)
;;;    TE   -- Test enable (Scan enable)
;;;
;;;    DTACK-  --  DTACK input
;;;    RESET-  --  RESET input
;;;    HOLD-   --  HOLD input
;;;
;;;    DISABLE-REGFILE-   --  Must be high to write enable the register
;;;                           file RAM.  During scan-in, DISABLE-REGFILE- is
;;;                           held low to avoid spurious writes to the RAM.
```

```
;;;
;;;    TEST-REGFILE-    --  Normally high.  When low, forces the register file
;;;                         output mux to pass data directly from the RAM.
;;;
;;;    PC-REG-IN[0..3]  --  The PC-REG inputs.
;;;
;;;
;;; BI-DIRECTS:
;;;
;;;    DATA-BUS[0..31]  --  The bi-directional data bus. (Controlled by RW-)
;;;
;;; OUTPUTS:
;;;
;;;  The memory control lines and the ADDR-OUT lines are tri-state.
;;;  The other output signals are ordinary TTL outputs.
;;;
;;;    PO      --  Parametric Output.
;;;    TO      --  Test Output (Scan out)
;;;    TIMING  --  The net corresponding to the longest combinational path.
;;;                Used to verify the speed of the device.
;;;
;;;    HDACK-   --  Hold Acknowledge
;;;
;;;    RW-      --  Memory control lines  (Tristate)
;;;    STROBE-
;;;
;;;    ADDR-OUT[0..31]  --  Address bus (Tristate)

;;;
;;;    SINGLE STEP SIMULATIONS
;;;
;;;  The STEP-FM9001 macro creates a lemma that describes the new state
;;;  computed by a single step of the low-level machine from a given initial
;;;  state.  This procedure is complicated by the fact that the next state
;;;  depends on the state of the memory.  Rather than produce a single lemma
;;;  that captures the behavior for all possible memory states, we create
;;;  separate lemmas only for those processor-state/memory-state configurations
;;;  that are possible during normal instruction execution.  This is important
;;;  because if the memory protocol is not followed, then unknown values may be
;;;  loaded into the processor registers.  What we are doing here is creating
;;;  a state-by-state, almost-Boolean specification of the low-level machine.
;;;  So we obviously we want to insure that the processor state remains
;;;  Boolean.
;;;
;;;  STEP-FM9001 is defined in "expand-fm9001.lisp".
;;;
;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;

;;;
;;;    Inductive progress proofs
;;;
;;;   For each of the states that wait for memory, we must prove that the
;;;   processor will eventually move on.  The lemmas below tell how long the
;;;   processor will remain in a given state, before the internal registers are
;;;   in such a condition that the machine will leave that state on the next
;;;   clock cycle.
;;;

;;;
;;;    Chunk Simulations
;;;
;;;  SIM-FM9001 is a macro that creates lemmas that describe the operation of
;;;  the machine for multiple clock cycles.  We create a multi-state simulation
;;;  for each non-branching segment of the state diagrams.  For this purpose,
;;;  we consider the states that wait for memory as "non-branching".  Notice
;;;  that some of the "multi-state" lemmas only include a single state.
;;;
;;;  SIM-FM9001 is defined in "expand-fm9001.lisp"
;;;
```

```
;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;

;;;  ZEROP-NOT-ZEROP-CASES is a bogus recursive function used to force the
;;;  prover to do these multi-step simulations by cases.

;;;
;;;    Execution time functions.
;;;
;;;  For each of the "chunks" above we define a function that states exactly
;;;  how many clock cycles are necessary to complete the instruction execution
;;;  cycle from the given starting state.  In these functions, CLOCK is the
;;;  memory delay oracle, and I-REG and FLAGS are the corresponding processor
;;;  registers.  The functions below are defined in terms of Common Lisp
;;;  functions appearing in "expand-fm9001.lisp".  The Common Lisp function
;;;  T_initial-state->final-state is an expression for the amount of time
;;;  necessary to execute the indicated section of of the state diagram.
;;;  The Common Lisp function CT_initial-state->final-state is an expression
;;;  for the memory delay oracle at the end of the sequence.  The Common Lisp
;;;  function TIMING-IF-TREE creates an "IF" tree of calls to timing functions
;;;  based on the branching decisions that appear in the state diagrams.
;;;

;;;+++++++++++++++++++++++++++++++++++++++++++++++++++++++++++++++++++++++++++++
;;;
;;;    MACROCYCLE-INVARIANT state pc
;;;
;;;  This is an invariant about the state of the machine at the beginning of
;;;  the instruction execution cycle:  all of the internal registers are
;;;  Boolean and properly sized; the machine is in state FETCH1 (ready to
;;;  execute an instruction);  the ADDR-OUT register contains the program
;;;  counter;  there are no pending writes in the register file;  HOLD-
;;;  and RESET- are not asserted;  the PC-REG is equal to (and remains equal
;;;  to) the specified PC; and the memory is well-formed and in a quiescent
;;;  state.
;;;
;;;  This is an important invariant; one of the more important proofs that
;;;  follows states that if we begin in this state, and run for
;;;  (MICROCYCLES state), then we will reach a state recognized by this
;;;  invariant.  This is the basis for the inductive proof that the
;;;  low-level machine implements the behavioral specification.

;;;
;;;    FM9001=CHIP-SYSTEM
;;;
;;;   The proofs that follow were originally what we thought of as the "final"
;;;   correctness results.  On further analysis, these really aren't very
;;;   satisfying because they presume that any high-level state can be mapped
;;;   down to a very specific low-level-state.  (You *could* do it with the
;;;   scan chain ...). All we can really guarantee about the machine is that
;;;   you can reset it, and then move forward at the end of the reset sequence.
;;;   We leave these events here for historical interest.
;;;

;;;  Here is an informal statement of the following lemma,
;;;  FM9001=CHIP-SYSTEM-SUMMARY, which is the chief result proved
;;;  about the FM9001.  Let H be the hardware netlist that we have
;;;  constructed for the FM9001.  The lemma states that for each
;;;  FM9001 user-visible state, S, and for each positive integer, N,
;;;  there exists a positive integer C such that the result of running
;;;  the user-model of the FM9001 (the function FM9001) N steps can
;;;  instead be obtained by simulating H and S under the DUAL-EVAL
;;;  semantics for C steps.  In precisely stating the theorem, we
;;;  arrange to supply the DUAL-EVAL semantics with a transform
;;;  (obtained with MAP-DOWN) of S, and afterwards we do a reverse
;;;  transformation (with MAP-UP) to obtain the final user-visible
;;;  state.  Futhermore, in making the statement precise we stipulate
;;;  that the external stimuli, I, to the chip do not enable a hold, a
;;;  reset, or a test input for the C clock cycles.  The fact that N
;;;  and C are different reflects the fact that a single FM9001
;;;  instruction takes several clock cycles to emulate at the
;;;  DUAL-EVAL netlist level.  The precise statement of this
;;;  correctness result is:

(prove-lemma fm9001=chip-system-summary nil
  (let ((h (chip-system$netlist))
        (c (total-microcycles (map-down s) (map-up-inputs i) n)))

;;;;;                except the RAM                    ;;;;;
;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;;

;; Next, let's prove that some primitive hardware components are
;; monotone, in the sense that when an input or "leaf" of the state is
;; changed from (X), they change their values or states only by
;; "filling in" for (X)s.

;; [Obscure comment that I no longer understand exactly:]  I'll adopt
;; an approach similar to Bishop/Warren's, except that I need to
;; consider arbitrary input argument lists rather than those of
;; exactly the right length (e.g.  4 for AO2$VALUE).  Actually, I
;; didn't realize that such lemmas already existed until starting to
;; define my versions.

;; First, a couple of lemmas.

;;;    FINAL-RESET.EVENTS
;;;
;;;  This file contains the verification of the FM9001 reset sequence.  There
;;;  are several reset proofs in this file, all stated in slightly different
;;;  ways.  There are also a number of refinements of the main correctness
;;;  theorem of the FM9001 microprocessor.
;;;
;;;~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~

;;;   Since some of the following proofs are simply simulations, we compile the
;;;   uncompiled DEFNs at this point to speed up these proofs.

(compile-uncompiled-defns* "a-weird-file-name-0")

;;;  The definition of a properly structured but completely unknown machine
;;;  state.

;; The following is a main theorem.  It follows readily from
;; XS-SUFFICE-FOR-RESET-CHIP-LEMMA-INSTANCE together with the theorem
;; SIMULATE-RESET-CHIP-FINAL-STATE, which essentially tells us that
;; when we simulate from the (UNKNOWN-MACHINE-STATE) we get to
;; (INITIALIZED-MACHINE-STATE).  The main improvement of this theorem
;; over XS-SUFFICE-FOR-RESET-CHIP-LEMMA-INSTANCE is that the
;; hypothesis here avoids the notion of ``approximation'' in favor
;; of a simple invariant on the structure of the state (see
;; NEW-MACHINE-STATE-INVARIANT-IS-NON-TRIVIAL and
;; NEW-MACHINE-STATE-INVARIANT-IMPLIES-MACHINE-STATE-INVARIANT
;; below).

;;;  CHIP-SYSTEM=FM9001-INTERPRETER$AFTER-RESET is the same as the lemma
;;;  chip-system=fm9001-interpreter in "proofs.events", except that it's
;;;  specialized to the case where the initial state is made up of the chip
;;;  state after reset (i.e., (INITIALIZED-MACHINE-STATE)) together with an
;;;  appropriate machine memory.  Thus, the hypothesis
;;;  (fm9001-state-structure state) has been omitted and the rather
;;;  elaborate hypothesis (macrocycle-invariant state) has been replaced by
;;;  the much weaker hypothesis (memory-okp 32 32 memory).  We can do this
;;;  because (INITIALIZED-MACHINE-STATE) satisfies the processor state
;;;  portions of these two hypotheses.
```

```

;;;~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~
;;;
;;;    FLAG-INTERPRETATION.EVENTS
;;;
;;;    Bishop Brock
;;;    Computational Logic, Inc.
;;;    May, 1993
;;;
;;;    Matt Kaufmann did much of the work when he proved the ALU interpretation
;;;    lemmas.  The lemmas in this file simply repackage the things he proved
;;;    into a potentially more useful format.  Since I didn't know his state of
;;;    mind concerning the libraries when he did his proofs, mine may have many
;;;    more DISABLE/ENABLE hints than really necessary.
;;;
;;;    The approach taken here is to prove a general lemma about the
;;;    STORE-RESULTP interpretations of the FLAGS, after a particular
;;;    instruction, and a minimal choice of set flags. In other words, assuming
;;;    that the current instruction performs some operation, these lemmas tell
;;;    how subsequent instructions would interpret the flags. E.g.,
;;;
;;;    (IMPLIES
;;;     (AND (BV2P a b)
;;;          <some flags in SET-FLAGS are set to be updated>)
;;;     (EQUAL (STORE-RESULTP (UPDATE-FLAGS flags set-flags <alu-output>)
;;;                           <store-cc code>)
;;;            <some meaningful arithmetic or logical interpretation>)).
;;;
;;;    These lemmas are not stored as rewrite rules because they simply serve
;;;    as consistency checks for the specification.  They would be necessary,
;;;    however, for someone trying to prove an assembly language program on the
;;;    FM9001.
;;;
;;;~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~

;;;
;;;  BIT VECTORS
;;;
;;;  Here we include interpretations valid for all functions of the ALU, as
;;;  well as some interpretation lemmas for the carry out on logical shifts.
;;;
;;;+++++++++++++++++++++++++++++++++++++++++++++++++++++++++++++++++++++++++++++

;;;  First, prove that the Z bit and N bit are always set as expected.

; Go get a cup of coffee while this one grinds out!

Chapter 15

THE FM9001 NETLIST

Here is the netlist that we supplied to LSI Logic to fabricate the FM9001. Although this netlist includes a specification of all the internal wiring it does not specify three matters necessary for fabrication, namely chip size, package used, and I/O pad to package pinout assignment. Additional material not presented here that we were obliged to supply to LSI Logic includes simulation control files, functional and post manufacture test vectors, and a rough two-dimensional layout of the top-level modules.
