CS303E: Elements of Computers and Programming

Functions

Dr. Bill Young
Department of Computer Science
University of Texas at Austin

Last updated: August 11, 2022 at 07:44
What is a Function?

What is a function?

<table>

</tr>
</tbody>
</table>

Domain: \{-2, -1, 0, 1, 2\}
Range: \{0, 1, 4\}

$f(x) = 2x + 1$
We’ve seen lots of system-defined functions; now it’s time to define our own.

General form:

```python
def functionName( list of parameters ): # header
    statement(s) # body
```

**Meaning:** a function definition defines a block of code that performs a specific task. It can reference any of the variables in the list of parameters. It may or may not return a value.

The parameters are **formal parameters**; they stand for arguments passed to the function later.
Functions

**Function name**
An identifier by which the function is called

**Arguments**
Contains a list of values passed to the function

```python
def name(arguments):
    statement
    statement
    ...
    return value
```

**Indentation**
Function body must be indented

**Function body**
This is executed each time the function is called

**Return value**
Ends function call & sends data back to the program
Calling a Function

# Function Definition

def add(a, b):
    return a + b

# Function Call
add(2, 3)
Suppose you want to sum the integers 1 to n.

In file `functionExamples.py`:

```python
def sumToN(n):
    """ Sum the integers from 1 to n. ""
    sum = 0 # identity element for +
    for i in range(1, n + 1): # Why n+1?
        sum += i
    # Hand the answer to the calling environment.
    return sum
```
Notice that the definition defines a *function* to perform the task, but *doesn’t actually perform the task*. We still have to call/invoke the function with specific arguments.

```python
>>> from functionExamples import *
>>> sumToN( 10 )
55
>>> sumToN( 1000 )
500500
>>> sumToN(1000000)
500000500000
```

You can think of the function call as being *replaced by* the value returned.

You can call a function as many times as you need.
def sumToN( n ): # function header
.... # function body

Here n is a formal parameter. It is used in the definition as a place holder for an actual parameter (e.g., 10 or 1000) in any specific call.

sumToN(n) returns an int value, meaning that a call to sumToN can be used anyplace an int expression can be used.

```python
>>> print( sumToN( 50 ) )
1275
>>> ans = sumToN( 30 )
>>> print( ans )
465
>>> print( "Even" if sumToN(3) % 2 == 0 else "Odd" )
Even
```
Once we’ve defined `sumToN`, we can use it almost as if were a primitive in the language without worry about the details of the definition.

*We need to know what it does, but don’t care anymore how it does it!* 

This is called **information hiding** or **functional abstraction**.
Another Way to Add Integers 1 to N

Suppose later we discover that we could have coded `sumToN` more efficiently (as discovered by the 8-year old C.F. Gauss in 1785):

```python
def sumToN(n):
    """ Sum the integers from 1 to n. ""
    return (n * (n+1)) // 2
```

Because we defined `sumToN` as a function, we can just swap in this definition without changing any other code. If we’d done the implementation in-line, we’d have had to go find every instance and change it.

```bash
>>> sumToN(10)
55
>>> sumToN(1000000000000)
5000000000005000000000000
```
Return Statements

When you execute a return statement, you go back to the calling environment. You may or may not hand a value back to the caller.

General forms:

```
return
return expression
```

A return that doesn’t specify a value actually returns the constant `None`.

Every function has an *implicit* return at the end.

```
def printTest ( x ):
    print ( x )
    # implicit return here
```

You can only have a return statement within a function.
Define your program in file 
Filename.py:

```python
def main():
    Python statement
    Python statement
    Python statement
    ...
    Python statement
    Python statement
    Python statement
main()
```

This defines a function main; could have a different name.

If you wanted to end the program, you could include a return statement.

You couldn’t use return if you just had the statements at the top level.

To run it:

```bash
> python Filename.py
```
In file `returnExamples.py`:

```python
def printSquares():
    """ Compute and print squares until 0 is entered
    by the user. ""
    while True:
        num = int(input("Enter an integer or 0 to exit: "))
        if ( num != 0 ): # "if num:" works
            print( "The square of", num, "is:", num ** 2 )
        else:
            return # no value is returned

printSquares()
```

This doesn’t return a value, but accomplishes it’s purpose by the “side effect” of printing.
A function that “doesn’t return a value” actually returns the constant None.
Suppose we want to multiply the integers from 1 to n:

```python
def multToN(n):
    """ Compute the product of the numbers from 1 to n. ""
    prod = 1 # identity element for *
    for i in range(1, n+1):
        prod *= i
    return prod
```

Convert fahrenheit to celsius:

```python
def fahrToCelsius(f):
    """ Convert fahrenheit temperature value to celsius using formula: C = 5/9(F-32). ""
    return 5 / 9 * (f - 32)
```

Or celsius to fahrenheit:

```python
def celsiusToFahr(c):
    """ Convert celsius temperature value to fahrenheit using formula: F = 9/5 * C + 32. ""
    return 9 / 5 * c + 32
```
In slideset 1, we showed the C version of a program to print a table of Fahrenheit to Celsius values. Here’s a Python version:

In file FahrToCelsius.py:

```python
from functionExamples import fahrToCelsius

def printFahrToCelsius():
    """ Print table fahrenheit to celsius for temp in [0, 20, 40, ... 300]."""
    lower = 0
    upper = 300
    step  = 20
    print("Fahr\tCelsius")
    for fahr in range(lower, upper + 1, step):
        # Use an already defined function.
        celsius = fahrToCelsius(fahr)
        print(format(fahr, "3d"), "\t", \n              format(celsius, "6.2f"))
    return  # not actually necessary

printFahrToCelsius()
```

Notice that printFahrToCelsius *doesn’t return a value.*
Running the Temperature Program

```bash
> python FahrToCelsius.py
Fahr     Celsius
  0       -17.78
  20      -6.67
  40       4.44
  60      15.56
  80      26.67
  100     37.78
  120     48.89
  140     60.00
  160     71.11
  180     82.22
  200     93.33
  220    104.44
  240    115.56
  260    126.67
  280    137.78
  300    148.89
```

**Exercise:** Do a similar problem converting Celsius to Fahrenheit.
There are occasionally reasons to define one function within another function. *But it’s generally a bad idea, unless you know what you’re doing.*

*For this class, always have your functions at the top level of your .py file.*
A Bigger Example: Print First 100 Primes

Suppose you want to print out a table of the first 100 primes, 10 per line.

You could sit down and write this program from scratch, without using functions. But it would be a complicated mess (section 5.8 of the book).

Better to use **functional abstraction**: find parts of the algorithm that can be coded separately and “packaged” as functions.

</tr>
</tbody>
</table>
Here’s some Python-like pseudocode to print 100 primes:

```python
def print100Primes():
    primeCount = 0
    num = 0
    while (primeCount < 100):
        if (we’ve already printed 10 on the current line):
            go to a new line
        nextPrime = ( the next prime > num )
        print nextPrime on the current line
        num = nextPrime
        primeCount += 1
```

Note that most of this is just straightforward Python programming! The only “new” part is how to find the next prime. So we’ll make that a function.
So let’s assume we can define a function:

```python
def findNextPrime( num ):
    """ Return the first prime greater than num. """
    < body >
```

in such a way that it returns the first prime larger than `num`.

Is that even possible? Is there always a “next” prime larger than `num`?
So let’s assume we can define a function:

```python
def findNextPrime( num):
    """ Return the first prime greater than num. ""

< body >
```
in such a way that it returns the first prime larger than `num`.

Is that even possible? Is there always a “next” prime larger than `num`?

Yes! There are an infinite number of primes. So if we keep testing successive numbers starting at `num + 1`, we’ll eventually find the next prime. *That may not be the most efficient way!*
Notice we’re following a “divide and conquer” approach: Reduce the solution of our bigger problem into one or more subproblems which we can tackle independently.

It’s also an instance of “information hiding.” We don’t want to think about how to find the next prime, while we’re worrying about printing 100 primes. Put that off!
Now solve the original problem, assuming we can write findNextPrime.

In file IsPrime3.py:

```python
def print100Primes ():
    """ Print a table of the first 100 primes, 10 primes per line. """
    primeCount = 0 # primes we’ve found
    onLine = 0 # primes printed on line
    num = 0 # need next prime > num
    while (primeCount < 100):
        # Do we stay on current line?
        if (onLine >= 10):
            print()
            onLine = 0
        # This is the only thing left to define:
        nextPrime = findNextPrime( num )
        num = nextPrime
        primeCount += 1
        print( format( nextPrime, "3d"), end = " " )
        onLine += 1
    print()
```
Here’s what the output should look like.

```python
>>> from IsPrime3 import print100Primes
>>> print100Primes()
  2   3   5   7  11  13  17  19  23  29
 31  37  41  43  47  53  59  61  67  71
 73  79  83  89  97 101 103 107 109 113
127 131 137 139 149 151 157 163 167 173
179 181 191 193 197 211 223 227 229
233 239 241 251 257 263 269 271 277 281
283 293 307 311 313 317 331 337 347 349
353 359 367 373 379 383 389 397 401 409
419 421 431 433 439 443 449 457 461 463
467 479 487 491 499 503 509 521 523 541
```

Of course, we couldn’t do this if we really hadn’t defined `findNextPrime`. So let’s see what that looks like.
The next prime (> num) can be found as indicated in the following pseudocode:

```python
def findNextPrime(num):
    if num < 2:
        return 2 as the answer
    else:
        guess = num + 1
        while ( guess is not prime )
            guess += 1
        return guess as the answer
```

Again we solved one problem by assuming the solution to another problem: deciding whether a number is prime.

Can you think of ways to improve this algorithm?
Note that we’re assuming we can write:

```python
def isPrime( num ):
    """ Boolean test for primality. """
    < body >

def findNextPrime( num ):
    """ Find the first prime > num. """
    if ( num < 2 ):
        return 2
    guess = num + 1
    while ( not isPrime( guess ) ):
        guess += 1
    return guess
```

This works (assuming we can define `isPrime`), but it’s pretty inefficient. How could you fix it?
When looking for the next prime, we don’t have to test every number, just the odd numbers (after 2).

```python
def findNextPrime ( num ):  
    """ Find the first prime > num. """
    if ( num < 2 ):
        return 2

    # If (num >= 2 and num is even), the
    # next prime after num is at least
    # (num - 1) + 2, which is odd.
    if ( num % 2 == 0):
        num -= 1
    guess = num + 2

    while ( not isPrime( guess )):
        guess += 2
    return guess
```

Now all that remains is to write isPrime.
Is a Number Prime?

We already solved a version of this in slideset 5. Let’s rewrite that code as a Boolean-valued function:

```python
def isPrime( num ):
    """ Test whether num is prime. """

    # Deal with evens and numbers < 2.
    if (num < 2 or num % 2 == 0):
        return (num == 2)

    # See if there are any odd divisors
    # up to the square root of num.
    divisor = 3
    while (divisor <= math.sqrt(num)):
        if (num % divisor == 0):
            return False
        else:
            divisor += 2
    return True
```

By the way, a Boolean-valued function is often called a **predicate**.
Testing Our Code

```python
>>> from IsPrime3 import findNextPrime, isPrime
>>> findNextPrime(-10)
2
>>> findNextPrime(2)
3
>>> findNextPrime(1000)
1009
>>> findNextPrime(100000000)
100000007
>>> isPrime(100000007)
True
>>> isPrime(1001)
False
>>> isPrime(1003)
False
>>> isPrime(1007)
False
>>> isPrime(1009)
True
```
Suppose we want to find and print k primes, starting from a given number:

In file IsPrime3.py:

```python
def findKPrimesStartingFrom( k, num ):
    """ Find the next k primes bigger than num. """
    if (k < 1):
        print( "You asked for zero primes!" )
    else:
        for i in range( k ):
            nextPrime = findNextPrime( num )
            print( nextPrime, end=" " )
            num = nextPrime
        print()
```

Notice that we can use functions we’ve defined such as findNextPrime and isPrime (almost) as if they were Python primitives.
Running Our Program

```python
>>> from IsPrime3 import findKPrimesStartingFrom
>>> findKPrimesStartingFrom(-10, 100000000)
You asked for zero primes!
>>> findKPrimesStartingFrom(5, -10)
2 3 5 7 11
>>> findKPrimesStartingFrom(10, 100000000)
100000007 100000037 100000039 100000049 100000073 100000081
  100000123 100000127 100000193 100000213
```
Functions and Return Values

Functions can return a value or not. A function that doesn’t return a value is sometimes called a **procedure**.

Of the functions defined earlier:

- `sumToInt`, `multToN`, `findNextPrime` all return int values
- `farhToCelsius` and `celsiusToFahr` return float values
- `isPrime` returns a bool value
- `printSquares`, `printFahrToCelsius`, `print100Primes`, and `findKPrimesStartingFrom` don’t return a value (return `None`).
Let’s Take a Break

TIME FOR A BREAK
This function has four formal parameters:

```python
def functionName ( x1 , x2 , x3 , x4 ) :
    < body >
```

Any call to this function should have exactly four actual arguments, which are matched to the corresponding formal parameters:

```python
functionName( 9, 12, -3, 10 )
functionName( 'a', 'b', 'c', 'd' )
functionName( 2, "xyz", 2.5, [3, 4, 5] )
```

This is called using **positional** arguments; it’s by far the most common approach.
It is also possible to use the formal parameters as **keywords**.

```python
def functionName ( x1, x2, x3, x4 ):
    functionBody
```

These two calls are equivalent:

```python
functionName( 'a', 'b', 'c', 'd' )
functionName( x3 = 'c', x1 = 'a', x2 = 'b', x4 = 'd' )
```

You can list the keyword arguments in any order, but all must still be specified.
You can mix keyword and positional arguments, but *must* have positional arguments first in order.

```python
def functionName ( x1, x2, x3, x4 ):
    functionBody

functionName( 'a', 'b', x4 = 'd', x3 = 'c' )  # OK
functionName( x2 = 'b', x1 = 'a', 'c', 'd' )   # illegal
```

Why do you think they make this rule?
You can also specify **default arguments** for a function. If you don’t specify a corresponding actual argument, the default is used.

```python
def printRectangleArea( width = 1, height = 2 ):
    area = width * height
    print("width: ", width, "\theight: ", height, \
          "\tarea: ", area)

printRectangleArea() # use defaults
printRectangleArea(4, 2.5) # positional args
printRectangleArea(height = 5, width = 3) # keyword args
printRectangleArea(width = 1.2) # default height
printRectangleArea(height = 6.2) # default width
```
Notice that you can mix default and non-default arguments, but must define the non-default arguments first.

def email (address, message = ""):
All values in Python are objects, including numbers, strings, etc.

When you pass an argument to a function, you’re actually passing a reference (pointer) to the object, not the object itself.

There are two kinds of objects in Python:

- **mutable**: you can change them in your program.
- **immutable**: you can’t change them in your program.

*If you pass a reference to a mutable object, it can be changed by your function. If you pass a reference to an immutable object, it can’t be changed by your function.*
<table>
<thead>
<tr>
<th>Type</th>
<th>Description</th>
<th>Syntax example</th>
</tr>
</thead>
<tbody>
<tr>

<td>An immutable floating point number (system-defined precision)</td>
<td>3.1415927</td>
</tr>
</tbody>
</table>
| str   | An immutable sequence of characters.                                        | 'Wikipedia'
                     |                                 | "Wikipedia"
                     |                                 | """Spanning multiple lines""""  |
| bool  | An immutable truth value                                                   | True, False                     |
| tuple | Immutable, can contain mixed types                                          | (4.0, 'string', True)           |
| bytes | An immutable sequence of bytes                                              | b'Some ASCII'
                     |                                 | b"Some ASCII"             |
| list  | Mutable, can contain mixed types                                            | [4.0, 'string', True]           |
| set   | Mutable, unordered, no duplicates                                          | {4.0, 'string', True}           |
| dict  | A mutable group of key and value pairs                                       | {'key1': 1.0, 3: False}         |
Consider the following code:

```python
def increment(x):
    x += 1
    print("Within the call x is: ", x)

x = 3
print("Before the call x is: ", x)
increment(x)
print("After the call x is: ", x)

def revList(lst):
    lst.reverse()
    print("Within the call lst is: ", lst)

lst = [1, 2, 3]
print("Before the call lst is: ", lst)
revList(lst)
print("After the call lst is: ", lst)
```
Invoking this code:

```python
>python Test.py
Before the call x is:  3
Within the call x is:  4
After the call x is:  3

Before the call lst is:  [1, 2, 3]
Within the call lst is:  [3, 2, 1]
After the call lst is:  [3, 2, 1]
```

Notice that the immutable integer parameter to `increment` was unchanged, while the mutable list parameter to `revList` was changed.
Variables defined in a Python program have an associated **scope**, meaning the portion of the program in which they are defined.

A **global variable** is defined outside of a function and is visible after it is defined. *Use of global variables is generally considered bad programming practice.*

A **local variable** is defined within a function and is visible from the definition until the end of the function.

A local definition overrides a global definition.
A local definition (locally) overrides the global definition.

```python
x = 1  # x is global

def func():
    x = 2  # this x is local
    print(x)  # will print 2

func()
print(x)  # will print 1
```

Running the program:

```
> python funcy.py
2
1
```
callCount = 0       # global variable

def caller():
    global callCount  # needed to access
    callCount += 1

caller()
print( "callCount = ", callCount )
caller()
print( "callCount = ", callCount )
caller()
print( "callCount = ", callCount )

> python Test.py
callCount = 1
callCount = 2
callCount = 3

What would happen if you took out the line containing global?
The Python `return` statement can also return multiple values. In fact it returns a *tuple* of values.

```python
def multipleValues(x, y):
    return x + 1, y + 1

print("Values returned are: ", multipleValues(4, 5.2))
x1, x2 = multipleValues(4, 5.2)
print("x1: ", x1, "\tx2: ", x2)
```

Values returned are: (5, 6.2)
x1: 5 x2: 6.2

You can operate on this using tuple functions, which we’ll cover later in the semester, or assign them to variables.
Python is pretty permissive about the order of things in your .py file. The following is the order I prefer:

- Header / Extended comment explaining what's in the file
- Any imports required
- Program constants
- Function definitions
- main function definition
- Call to main function

Include comments throughout.
Next stop: Objects and Classes.
