ABSTRACT

Multitask Reinforcement Learning (MTRL) approaches have gained increasing attention for its wide applications in many important Reinforcement Learning (RL) tasks. However, while recent advancements in MTRL theory have focused on the improved statistical efficiency by assuming a shared structure across tasks, exploration—a crucial aspect of RL—has been largely overlooked. This paper addresses this gap by showing that when an agent is trained on a sufficiently diverse set of tasks, a generic policy-sharing algorithm with myopic exploration design like $\epsilon$-greedy that are inefficient in general can be sample-efficient for MTRL. To the best of our knowledge, this is the first theoretical demonstration of the "exploration benefits" of MTRL. It may also shed light on the enigmatic success of the wide applications of myopic exploration in practice. To validate the role of diversity, we conduct experiments on synthetic robotic control environments, where the diverse task set aligns with the task selection by automatic curriculum learning, which is empirically shown to improve sample-efficiency.

1 INTRODUCTION

Reinforcement Learning often involves solving multitask problems. For instance, robotic control agents are trained to simultaneously solve multiple goals in multi-goal environments (Andreas et al., 2017; Andrychowicz et al., 2017). In mobile health applications, RL is employed to personalize sequences of treatments, treating each patient as a distinct task (Yom-Tov et al., 2017; Forman et al., 2019; Liao et al., 2020; Ghosh et al., 2023). Many algorithms (Andreas et al., 2017; Andrychowicz et al., 2017; Hessel et al., 2019; Yang et al., 2020) have been designed to jointly learn from multiple tasks, which shows significant improvement over those that learn each task individually. Towards the potential explanations of such improvement, recent advancements in Multitask Reinforcement Learning (MTRL) theory study the improved statistical efficiency in estimating unknown parameters by assuming a shared structure across tasks (Brunskill & Li, 2013; Calandriello et al., 2014; Uehara et al., 2021; Xu et al., 2021; Zhang & Wang, 2021; Lu et al., 2021; Agarwal et al., 2022; Cheng et al., 2022; Yang et al., 2022a). Similar setups originate from Multitask Supervised Learning, where it has been shown that learning from multiple tasks reduces the generalization error by a factor of $1/\sqrt{N}$ compared to single-task learning with $N$ being the total number of tasks (Maurer et al., 2016; Du et al., 2020). Nevertheless, these studies overlook an essential aspect of RL—exploration.

To understand how learning from multiple tasks, as opposed to single-task learning, could potentially benefit exploration design, we consider a generic MTRL scenario, where an algorithm interacts with a task set $M$ in rounds $T$. In each round, the algorithm chooses an exploratory policy $\pi$ that is used to collect one episode of its own choice of $M \in M$. A sample-efficient algorithm should output a near-optimal policy for each task in polynomial number of rounds.

Exploration design plays an important role in achieving sample-efficient learning. Previous sample-efficient algorithms for single-task learning ($|M| = 1$) heavily rely on strategic design on the exploratory policies, such as Optimism in Face of Uncertainty (OFU) (Auer et al., 2008; Bartlett & Tewari, 2009; Dann et al., 2017) and Posterior Sampling (Russo & Van Roy, 2014; Osband & Van Roy, 2017). Strategic design is criticized for either being restricted to environments with strong structural assumptions, or involving intractable computation oracle, such as non-convex optimization (Jiang, 2018; Jin et al., 2021a). For instance, GOLF (Jin et al., 2021a), a model-free general function
approximation online learning algorithm, involves finding the optimal Q-value function \( f \) in a function class \( \mathcal{F} \). It requires the following two intractable computation oracles in (1).

\[
\mathcal{F}^t = \{ f \in \mathcal{F} : f \text{ has low empirical Bellman error} \} \quad \text{and} \quad \arg\max_{f \in \mathcal{F}^t} f(s_1, \pi(s_1 | f)). \tag{1}
\]

In contrast, myopic exploration design like \( \epsilon \)-greedy that injects random noise to a current greedy policy is easy to implement and performs well in a wide range of applications (Mnih et al., 2015, Kalashnikov et al., 2018), while it is shown to have exponential sample complexity in the worst case for single-task learning (Osband et al., 2019). Throughout the paper, we ask the main question:

**Can algorithms with myopic exploration design be sample-efficient for MTRL?**

In this paper, we address the question by showing that a simple algorithm that explores one task with \( \epsilon \)-greedy policies from other tasks can be sample-efficient if the task set \( \mathcal{M} \) is adequately diverse. Our results may shed some light on the longstanding mystery that \( \epsilon \)-greedy is successful in practice, while being shown sample-inefficient in theory. We argue that in an MTRL setting, \( \epsilon \)-greedy policies may no longer behave myopically, as they explore myopically around the optimal policies from other tasks. When the task set is adequately diverse, this exploration may provide sufficient coverage. It is worth-noting that this may partially explain the success of curriculum learning in RL (Narvekar et al., 2020), that is the optimal policy of one task may easily produce a good exploration for the next task, thus reducing the complexity of exploration. This connection will be formally discussed later.

To summarize our contributions, this work provides a general framework that converts the task of strategic exploration design into the task of constructing diverse task set in an MTRL setting, where myopic exploration like \( \epsilon \)-greedy can also be sample-efficient. We discuss a sufficient diversity condition under a general value function approximation setting (Jin et al., 2021a, Dann et al., 2022). We show that the condition guarantees polynomial sample-complexity bound by running the aforementioned algorithm with myopic exploration design. We further discuss how to satisfy the diversity condition in different case studies, including tabular cases, linear cases and linear quadratic regulator cases. In the end, we validate our theory with experiments on synthetic robotic control environments, where we observe that a diverse task set coincidences with the task selection of the state-of-the-art automatic curriculum learning algorithm, which has been empirically shown to improve sample efficiency.

## 2 Problem Setup

The following are notations that will be used throughout the paper.

**Notation.** For a positive integer \( H \), we denote \([H] := \{1, \ldots, H\}\). For a discrete set \( \mathcal{A} \), we denote \( \Delta_{\mathcal{A}} \) by the set of distributions over \( \mathcal{A} \). We use \( \mathcal{O} \) and \( \Omega \) to denote the asymptotic upper and lower bound notations and use \( \mathcal{O} \) and \( \Omega \) to hide the logarithmic dependence. Let \( \{1\}_i \in [d] \) be the standard basis that spans \( \mathbb{R}^d \). We let \( N_{\mathcal{F}}(\rho) \) denote the \( \ell_\infty \) covering number of a function class \( \mathcal{F} \) at scale \( \rho \). For a class \( \mathcal{F} \), we denote the \( N \)-times Cartesian product of \( \mathcal{F} \) by \( (\mathcal{F})^\otimes N \).

### 2.1 Proposed Multitask Learning Scenario

Throughout the paper, we consider each task as an episodic MDP denoted by \( M = (\mathcal{S}, \mathcal{A}, H, P, R) \), where \( \mathcal{S} \) is the state space, \( \mathcal{A} \) is the action space, \( H \in \mathcal{N} \) represents the horizon length in each episode, \( P = \{P_h\}_{h \in [H]} \) is the collection of transition kernels, and \( R = \{R_h\}_{h \in [H]} \) is the collection of immediate reward functions. Each \( P_h : \mathcal{S} \times \mathcal{A} \mapsto \Delta(\mathcal{S}) \) and each \( R_h : \mathcal{S} \times \mathcal{A} \mapsto [0, 1] \). Note that we consider a scenario in which all the tasks share the same state space, action space, and horizon length.

An agent interacts with an MDP \( M \) in the following way: starting with a fixed initial state \( s_1 \), at each step \( h \in [H] \), the agent decides an action \( a_h \) and the environment samples the next state \( s_{h+1} \sim P_h(a_h) \) and next reward \( r_h = R_h(s_h, a_h) \). An episode is a sequence of states, actions, and rewards \((s_1, a_1, r_1, \ldots, s_H, a_H, r_H, s_{H+1})\). In general, we assume that the sum of \( r_h \) is upper bounded by \( 1 \) for any action sequence almost surely. The goal of an agent is to maximize the cumulative reward \( \sum_{h=1}^{H} r_h \) by optimizing their actions.
The agent chooses actions based on Markovian policies denoted by \( \pi = (\pi_h)_{h \in [H]} \) and each \( \pi_h \) is a mapping \( S \mapsto \Delta_A \), where \( \Delta_A \) is the set of all distributions over \( A \). Let \( \Omega \) denote the space of all such policies. For a finite action space, we let \( \pi_h(a \mid s) \) denote the probability of selecting action \( a \) given state \( s \) at the step \( h \). In case of the infinite action space, we slightly abuse the notation by letting \( \pi_h(\cdot \mid s) \) denote the density function.

**Proposed multitask learning scenario and objective.** We consider the following multitask RL learning scenario. An algorithm interacts with a set of tasks \( \mathcal{M} \) sequentially for \( T \) rounds. At the end of each round \( t \), the algorithm chooses an exploratory policy, which is used to collect one episode of its own choice of \( M \in \mathcal{M} \). At the end of \( T \) rounds, the algorithm outputs a set of policies \( \{\pi_M\}_{M \in \mathcal{M}} \). The goal of an algorithm is to learn a near-optimal policy \( \pi_M \) for each task \( M \in \mathcal{M} \). The sample complexity of an algorithm is defined as follows.

**Definition 1 (MTRL Sample Complexity).** An algorithm \( \mathcal{L} \) is said to have sample-complexity of \( C^M_{\mathcal{L}} : \mathbb{R} \times [0, 1] \rightarrow \mathbb{N} \) for a task set \( \mathcal{M} \) if for any \( \beta > 0, \delta \in (0, 1) \), it outputs a \( \beta \)-optimal policy \( \pi_M \) for each MDP \( M \in \mathcal{M} \) with probability at least \( 1 - \delta \), by interacting with the task set for \( C^M_{\mathcal{L}}(\beta, \delta) \) rounds. We omit the notations for \( \mathcal{L} \) and \( \mathcal{M} \) when they are clear from the context to ease presentation.

A sample-efficient algorithm should have a sample-complexity polynomial in the parameters of interests. For the tabular case, where the state space and action space are finite, \( C(\beta, \delta) \) should be polynomial in \(|S|, |A|, |M|, H\), and \( 1/\beta \) for a sample-efficient learning. Current state-of-the-art algorithm (Zhang et al., 2021) on a single-task tabular MDP achieves sample-complexity of \( \tilde{O}(|S||A|/\beta^2) \). This bound translates to a MTRL sample-complexity bound of \( \tilde{O}(|\mathcal{M}| |S||A|/\beta^2) \) by running their algorithm individually for each \( M \in \mathcal{M} \). However, their exploration design closely follows the principle of Optimism in Face of Uncertainty, which is normally criticized for over-exploring.

### 2.2 Value Function Approximation

We consider the setting where value functions are approximated by general function classes. Denote the value function of an MDP \( M \) with respect to a policy \( \pi \) by

\[
Q^\pi_{h,M}(s, a) = \mathbb{E}^M_{\pi} \left[ r_h + \max_{a' \in A} V^\pi_{h+1,M}(s_{h+1}) \mid s_h = s, a_h = a \right],
\]

\[
V^\pi_{h,M}(s) = \mathbb{E}^M_{\pi} \left[ Q^\pi_{h,M}(s_h, a_h) \mid s_h = s \right],
\]

where by \( \mathbb{E}^M_{\pi} \), we take expectation over the randomness of trajectories sampled by policy \( \pi \) on MDP \( M \) and we let \( V^\pi_{h+1,M}(s) \equiv 0 \) for all \( s \in S \) and \( \pi \in \Omega \). We denote the optimal policy for MDP \( M \) by \( \pi^*_M \). The corresponding value functions are denoted by \( V^*_M \) and \( Q^*_M \), which is shown to satisfy Bellman Equation \( T^M_{h+1}Q^*_h,M = Q^*_h,M \) for any \( g : S \times A \rightarrow [0, 1] \), \( (T^M_{h+1}g)(s, a) = \mathbb{E}[r_h + \max_{a' \in A} g(s_{h+1}, a') \mid s_h = s, a_h = a] \).

The agent has access to a collection of function classes \( \mathcal{F} = (\mathcal{F}_h : S \times A \rightarrow [0, H])_{h \in [H]} \). We assume that different tasks share the same set of function class. For each \( f \in \mathcal{F} \), we denote by \( f_h \in \mathcal{F}_h \) the \( h \)-th component of the function \( f \). We let \( \pi^f = \{\pi^f_h\}_{h \in [H]} \) be the greedy policy with \( \pi^f_h(s) = \arg\max_{a \in A} f_h(s, a) \). When it is clear from the context, we slightly abuse the notation and let \( f \in (\mathcal{F})^{\otimes |\mathcal{M}|} \) be a joint function for all the tasks. We further let \( f_M \) denote the function for the task \( M \) and \( f_{h,M} \) denote its \( h \)-th component.

Define Bellman error operator \( \mathcal{E}^M_h \) such that \( \mathcal{E}^M_h f = f_h - T^M_{h} f_{h+1} \) for any \( f \in \mathcal{F} \). The goal of the learning algorithm is to approximate \( Q^*_h,M \) through the function class \( \mathcal{F}_h \) by minimizing the empirical Bellman error for each step \( h \) and task \( M \). To provide theoretical guarantee on this practice, we make the following realizability and completeness assumptions. The two assumptions and their variants are commonly used in the literature (Dann et al., 2017; Jin et al., 2021a).

**Assumption 1 (Realizability and Completeness).** For any MDP \( M \) considered in this paper, we assume \( \mathcal{F} \) is realizable and complete under the Bellman operator such that \( Q^*_h,M \in \mathcal{F}_h \) for all \( h \in [H] \) and for every \( h \in [H], f_{h+1} \in \mathcal{F}_{h+1} \) there is a \( f_h \in \mathcal{F}_h \) such that \( f_h = T^M_{h} f_{h+1} \).

\(^1\)This bound is under the regime with \( 1/\beta \gg |S| \).
2.3 Myopic Exploration Design

As opposed to carefully designed exploration, myopic exploration injects random noise to the current greedy policy. For a given greedy policy $\pi$, we use $\text{expl}(\pi)$ to denote the myopic exploration policy based on $\pi$. Depending on the action space, the function $\text{expl}$ can take different forms. The most common choice for finite action spaces is $\epsilon$-greedy, which mixes the greedy policy with a random action: $\text{expl}(\pi_h)(a | s) = (1 - \epsilon_h) \pi_h(a | s) + \epsilon_h a$, where $\epsilon_h$ is our main study of exploration strategies, we let $\text{expl}$ be $\epsilon$-greedy function if not explicitly specified. For a continuous action space, we consider exploration with Gaussian noise: $\text{expl}(\pi_h)(a | s) = (1 - \epsilon_h) \pi_h(a | s) + \epsilon_h \exp(-a^2/2\sigma_h^2)/\sqrt{2\pi\sigma_h^2}$. Gaussian noise is useful for Linear Quadratic Regulator (LQR) setting (discussed in Appendix F).

3 Multitask RL Algorithm with Policy-Sharing

In this section, we introduce a generic algorithm (Algorithm 1) for the proposed multitask RL scenario without any strategic exploration, whose theoretical properties will be studied throughout the paper. In a typical single-task learning, a myopically exploring agent samples trajectories by running its current greedy policy estimated from the historical data equipped with naive explorations like $\epsilon$-greedy.

In light of the exploration benefits of MTRL, we study Algorithm 1 as a counterpart of the single-task learning scenario in the MTRL setting. Algorithm 1 maintains a dataset for each MDP separately and different tasks interact in the following way: in each round, Algorithm 1 explores every MDP with an exploratory policy that is the mixture (defined in Definition 2) of greedy policies of all the MDPs in the task set (Line 8). One way to interpret Algorithm 1 is that we share knowledge across tasks by policy sharing instead of parameter sharing or feature extractor sharing in the previous literature.

**Definition 2 (Mixture Policy).** For a set of policies $\{\pi_i\}_{i=1}^N$, we denote $\text{Mixture}\{\{\pi_i\}_{i=1}^N\}$ by the mixture of $N$ policies, such that before the start of an episode, it samples $I \sim \text{Unif}([N])$, then runs policy $\pi_{I}$ for the rest of the episode.

The greedy policy is obtained from an offline learning oracle $Q$ (Line 4) that maps a dataset $D = \{(s_i, a_i, r_i, s'_i)\}_{i=1}^N$ to a function $f \in F$, such that $Q(D)$ is an approximate solution to the following minimization problem $\min_{f \in F} \sum_{i=1}^N (f_h(s_i, a_i) - r_i - \max_{a' \in A} f_{h+1}(s'_i, a'))^2$. In practice, one can run fitted Q-iteration for an approximate solution.

**Connection to Hindsight Experience Replay (HER) and multi-goal RL.** We provide some justifications for the choice of the mixture policy. HER is a common practice in the multi-goal RL setting, where the reward distribution is a function of goal-parameters. HER relabels the rewards in trajectories in the experience buffer such that they were as if sampled for a different task. Notably, this exploration strategy is akin to randomly selecting task and collecting a trajectory on using its own epsilon-greedy policy, followed by relabeling rewards to simulate a trajectory on, which is equivalent to Algorithm 1. Yang et al. (2022b) and Zhumabekov et al. (2023) also designed an algorithm with ensemble policies, which is shown to improve generalizability. It is worth noting that the ensemble implementation of Algorithm 1 and that of Zhumabekov et al. (2023) differs. In Algorithm 1, policies are mixed trajectory-wise, with one policy randomly selected for the entire episode. In contrast, Zhumabekov et al. (2023) mixes policies on a step-wise basis for a continuous action space, selecting actions as a weighted average of actions chosen by different policies. This distinction is vital in showing the rigorous theoretical guarantee outlined in this paper.

**Connection to curriculum learning.** Curriculum learning is the approach that learns tasks in a specific order to improve the multitask learning performance. Bengio et al. (2009) showed that this can be achieved through adaptive task selection that may reflect the benefits of curriculum learning. Intuitively, any curricula that selects tasks through an order of $M_1, \ldots, M_T$ is implicitly included in Algorithm 1 as it explores all the MDPs in each round with the mixture of all epsilon-greedy policies. This means that the sample-complexity of Algorithm 1 provides an upper bound on the sample complexity of underlying optimal task selection. A formal discussion is deferred to Appendix B.

---

2. Note that we consider a more general setup, where the exploration probability $\epsilon$ can depend on $h$. 

---

Published as a conference paper at ICLR 2024
Figure 1: A diverse grid-world task set on a long hallway with $N+1$ states. From the left to the right, it represents a single-task and a multitask learning scenario, respectively. The triangles represent the starting state and the stars represent the goal states, where an agent receives a positive reward. The agent can choose to move forward or backward.

### 4 Generic Sample Complexity Guarantee

In this section, we rigorously define the diversity condition and provide a sample-complexity upper bound for Algorithm 1. We start with introducing an intuitive example on how diversity encourages exploration in a multitask setting.

**Motivating example.** Figure 1 introduces a motivating example of grid-world environment on a long hallway with $N+1$ states. Since this is a deterministic tabular environment, whenever a task collects an episode that visits its goal state, running an offline policy optimization algorithm with pessimism will output its optimal policy.

Left penal of Figure 1 is a single-task learning, where the goal state is $N$ steps away from the initial state, making it exponentially hard to visit the goal state with $\epsilon$-greedy exploration. Figure 1 on the right demonstrates a multitask learning scenario with $N$ tasks, whose goal states "diversely" distribute along the hallway. A main message of this paper is the advantage of exploring one task by running the $\epsilon$-greedy policies of other tasks. To see this, consider any current greedy policies (\(\pi_1, \pi_2, \ldots, \pi_N\)). Let $i$ be the first non-optimal policy, i.e. all $j < i$, $\pi_j$ is optimal for $M_j$. Since $\pi_{i-1}$ is optimal, by running an $\epsilon$-greedy of $\pi_{i-1}$ on MDP $M_i$, we have a probability of $\prod_{h=1}^{i-1}(1 - \epsilon_h)\epsilon_i$ to visit the goal state of $M_i$, allowing it to improve its policy to optimal in the next round. Such improvement can only happen for $N$ times and all policies will be optimal within polynomial (in $N$) number of rounds if we choose $\epsilon_h = 1/(h + 1)$. Hence, myopic exploration with a diverse task set leads to sample-efficient learning. The rest of the section can be seen as generalizing this idea to function approximation.

#### 4.1 Multitask Myopic Exploration Gap

[Dann et al. 2022] proposed an assumption named Myopic Exploration Gap (MEG) that allows efficient myopic exploration for a single MDP under strong assumptions on the reward function, or on the mixing time. We extend this definition to the multitask learning setting. For the conciseness of the notation, we let $\text{expl}(f)$ denote the following mixture policy $\text{Mixture}\{\{\text{expl}(\pi^f_M)\}_{M \in \mathcal{M}}\}$

### Algorithm 1: Generic Algorithm for MTRL with Policy-Sharing

1. **Input:** function class $\mathcal{F} = \mathcal{F}_1 \times \cdots \times \mathcal{F}_{H+1}$, task set $\mathcal{M}$, exploration function $\text{expl}$
2. Initialize $\mathcal{D}_{0,M} = \emptyset$ for all $M \in \mathcal{M}$
3. for round $t = 1, 2, \ldots, \lfloor T/|\mathcal{M}| \rfloor$ do
4.  Offline learning oracle outputs $\hat{f}_{t,M} \leftarrow Q(D_{t-1,M})$ for each $M$ \hspace{1cm} $\triangleright$ Offline learning
5.  Set myopic exploration policy $\hat{\pi}_{t,M} \leftarrow \text{expl}(\hat{f}_{t,M})$ for each $M$
6.  Set $\hat{\pi}_t \leftarrow \text{Mixture}(\{\hat{\pi}_{t,M}\}_{M \in \mathcal{M}})$ \hspace{1cm} $\triangleright$ Share policies
7.  for $M \in \mathcal{M}$ do
8.  Sample one episode $\tau_{t,M}$ on MDP $M$ with policy $\hat{\pi}_t$ \hspace{1cm} $\triangleright$ Collect new trajectory
9.  Add $\tau_{t,M}$ to the dataset: $\mathcal{D}_{t,M} \leftarrow \mathcal{D}_{t-1,M} \cup \{\tau_{t,M}\}$
10. end for
11. end for
12. Return $\hat{\pi}_M = \text{Mixture}(\{\hat{\pi}_{t,M}\}_{t \in \lfloor T/|\mathcal{M}| \rfloor})$ for each $M$
for a joint function \( f \in (\mathcal{F})^{\otimes |\mathcal{M}|} \). Intuitively, a large myopic exploration gap implies that within all the policies that can be learned by the current exploratory policy, there exists one that can make significant improvement on the current greedy policy.

**Definition 3 (Multitask Myopic Exploration Gap (Multitask MEG)).** For any \( \mathcal{M} \), a function class \( \mathcal{F} \), a joint function \( f \in (\mathcal{F})^{\otimes |\mathcal{M}|} \), we say that \( f \) has \( \alpha(f, \mathcal{M}, \mathcal{F}) \)-myopic exploration gap, where \( \alpha(f, \mathcal{M}, \mathcal{F}) \) is the value to the following maximization problem:

\[
\max_{M \in \mathcal{M}} \sup_{f \in \mathcal{F}, \epsilon \geq 1} \frac{1}{\sqrt{M}} (V_{f, M} - V_{f, M}^{\epsilon}), \text{ s.t. for all } f' \in \mathcal{F} \text{ and } h \in [H],
\]

\[
\mathbb{E}_{M}^{\epsilon} \{((\mathcal{E}_h f')(s_h, a_h))^2 \} \leq c\mathbb{E}_{\text{expl}}^{\epsilon}(f)((\mathcal{E}_h f')(s_h, a_h))^2.
\]

Let \( M(f, \mathcal{M}, \mathcal{F}) \), \( c(f, \mathcal{M}, \mathcal{F}) \) be the corresponding \( M \in \mathcal{M} \) and \( c \) that attains the maximization.

**Design of myopic exploration gap.** To illustrate the spirit of this definition, we specialize to the tabular case, where conditions in Definition 3 can be replaced by the concentrability \([\text{In et al. } 2021b]\) condition: for all \( s, a, h \in S \times A \times [H] \), we require

\[
\mu_{\text{exp}}^f(s, a) \leq c\mu_{h, M}^f(s, a) \quad \text{and} \quad \mu_{\text{expl}}^f(s, a) \leq c\mu_{h, M}(s, a),
\]

where \( \mu_{h, M}^f(s, a) \) is the occupancy measure, i.e. the probability of visiting \((s, a)\) at the step \( h \) by running policy \( \pi \) on MDP \( M \). The design of myopic exploration gap connects deeply to the theory of offline Reinforcement Learning. For a specific MDP \( M \), Equation \( 2 \) defines a set of policies with concentrability assumption \([\text{Xie et al. } 2021]\) that can be accurately evaluated through the offline data collected by the current behavior policy. As an extension to the Single-task MEG in \([\text{Dann et al. } 2022]\), Multitask MEG considers the maximum myopic exploration gap over a set of MDPs and the behavior policy is a mixture of all the greedy policies. Definition 4 reduces to the Single-task MEG when the task set \( M \) is a singleton.

### 4.2 Sample Complexity Guarantee

We propose Diversity in Definition 5, which relies on having a lower bounded Multitask MEG for any suboptimal policy. We then present Theorem 1 that shows an upper bound for sample complexity of Algorithm 1 by assuming diversity.

**Definition 4 (Multitask Suboptimality).** For a multitask RL problem with MDP set \( \mathcal{M} \) and value function class \( \mathcal{F} \). Let \( \mathcal{F}_{\beta} \subset (\mathcal{F})^{\otimes |\mathcal{M}|} \) be the \( \beta \)-suboptimal class, such that for any \( f \in \mathcal{F}_{\beta} \), there exists \( f_{\beta} \) such that \( \pi_{\beta} f_{\beta} \) is \( \beta \)-suboptimal for MDP \( M \), i.e.

\[
V_{1, M}^{\epsilon} = \max_{\epsilon \in [0, 1]} V_{f_{\beta}, M}^{\epsilon} - \beta.
\]

**Definition 5 (Diverse Tasks).** For some function \( \alpha : [0, 1] \mapsto \mathbb{R} \), and \( \tilde{c} : [0, 1] \mapsto \mathbb{R} \), we say that a tasks set is \((\alpha, \tilde{c})\)-diverse if any \( f \in \mathcal{F}_{\beta} \) has multitask myopic exploration gap \( \alpha(f, \mathcal{M}, \mathcal{F}) \geq \alpha(\beta) \) and \( c(f, \mathcal{M}, \mathcal{F}) \leq \tilde{c}(\beta) \) for any constant \( \beta > 0 \).

To simplify presentation, we state the result here assuming parametric growth of the Bellman Eluder dimension and covering number, that is, \( d_{BE}(\mathcal{F}, \Pi_{\mathcal{F}}, \rho) \leq d_{BE}^* \log(1/\rho) \) and \( d_{\text{cover}}(\mathcal{F}, \rho) \leq d_{\text{cover}}^* \log(1/\rho) \), where \( d_{BE}(\mathcal{F}, \Pi_{\mathcal{F}}, \rho) \) is the Bellman-Eluder dimension of class \( \mathcal{F} \) and \( N_{\mathcal{F}}(\rho) = \sum_{h=1}^{H} N_{\mathcal{F}_h}(\rho) N_{\mathcal{F}_{h+1}}(\rho) \). A formal definition of Bellman-Eluder dimension is deferred to Appendix \( \text{[H]} \). This parametric growth rate holds for most of the regular classes including tabular and linear \([\text{Russo & Van Roy } 2013]\). Similar assumptions are made in \([\text{Chen et al. } 2022]\).

**Theorem 1 (Upper Bound for Sample Complexity).** Consider a multitask RL problem with MDP set \( \mathcal{M} \) and value function class \( \mathcal{F} \) such that \( \mathcal{M} \) is \((\alpha, \tilde{c})\)-diverse. Then Algorithm 1 with \( \epsilon \)-greedy exploration function has a sample-complexity

\[
C(\beta, \delta) = \tilde{\mathcal{O}} \left( |\mathcal{M}|^2 H^2 d_{BE} d_{\text{covering}} \ln \frac{\tilde{c}(\beta)}{\alpha(\beta)} \ln \left( \frac{1}{\delta} \right) \right).
\]

### 4.3 Comparing Single-task and Multitask MEG

The sample complexity bound in Theorem 1 reduces to the single-task sample complexity in \([\text{Dann et al. } 2022]\) when \( \mathcal{M} \) is a singleton. To showcase the potential benefits of multitask learning, we provide

---

Published as a conference paper at ICLR 2024
We first show that Multitask MEG is lower bounded by Single-task MEG up to a factor of \(\frac{1}{\sqrt{|M|}}\).

**Proposition 1.** Let \(M\) be any set of MDPs and \(F\) be any function class. We have that \(\alpha(f, M, F) \geq \alpha(\{M\}, \{M\}, F) / \sqrt{|M|}\) for all \(f \in \langle F \rangle^{\otimes|M|}\) and \(M \in M\).

Proposition 1 immediately implies that whenever all tasks in a task set can be learned with myopic exploration individually (see examples in [Jin et al., 2020b]), they can also be learned with myopic exploration through MT-MEG with Algorithm 1 with an extra factor of \(|M|^2\), which is still polynomial in all the related parameters.

We further argue that Single-task MEG can easily be exponentially small in \(H\), in which case, myopic exploration fails.

**Proposition 2.** Let \(M\) be a tabular sparse-reward MDP, i.e., \(R_{h,h}(s,a) = 0\) at all \((s,a,h)\) except for a goal tuple \((s_t,a_t,h_t)\) and \(R_{h,h}(s_t,a_t) = 1\). Recall \(\mu_{h,M}(s,a) = E_{s' \sim R_{h,h}}[1_{s_t = s, a_t = a}]\). Then

\[
\alpha(f, \{M\}, F) \leq \max_{\pi} \left( \mu_{h,M}(s_t,a_t) - \mu_{h,M}(s_t,a_t) \right) \sqrt{\frac{\exp(\pi)}{\mu_{h,M}(s_t,a_t)}} \leq \sqrt{\frac{\exp(\pi)}{\mu_{h,M}(s_t,a_t)}}.
\]

Sparse-reward MDP is widely studied in goal-conditioned RL, where the agent receives a non-zero reward only when it reaches a goal-state ([Andrychowicz et al., 2017] [Chane-Sane et al., 2021]). Proposition 2 implies that a single-task MEG can easily be exponentially small in \(H\) as long as one can find a policy \(\pi\) such that its \(\epsilon\)-greedy version, \(\exp(\pi)\), visits the goal tuple \((s_t,a_t,h_t)\) with a probability that is exponentially small in \(H\). This is true when the environment requires the agent to execute a fixed sequence of actions to reach the goal tuple as it is the case in Figure 1. Indeed, in the environment described in the left panel of Figure 1, a policy that always moves left will have \(\alpha(f, \{M\}, F) \leq \sqrt{\frac{\exp(\pi)}{\mu_{h,M}(s_t,a_t)}} \leq \sqrt{\prod_{h=1}^{H}(\epsilon_h/2)} \leq 2^{-H/2}\). This is also consistent with our previous discussion that \(\epsilon\)-greedy requires \(\Omega(2^H)\) number of episodes to learn the optimal policy in the worst case. As we will show later in Section 5, Multitask MEG for the tabular case can be lower bounded by \(\Omega(\sqrt{1/(|A||M|H)})\) for adequately diverse task set \(M\), leading to an exponential separation between Single-task and Multitask MEG.

5 **Lower Bounding Myopic Exploration Gap**

Following the generic result in Theorem 1 the key to the problem is to lower bound myopic exploration gap \(\hat{\alpha}(\beta)\). In this section, we lower bound \(\hat{\alpha}(\beta)\) for the linear MDP case. We defer an improved analysis for the tabular case and the Linear Quadratic Regulator cases to Appendix F.

Linear MDPs have been an important case study for the theory of RL ([Wang et al., 2019] [Jin et al., 2020b] [Chen et al., 2022b]). It is a more general case than tabular MDP and has strong implication for Deep RL. In order to employ \(\epsilon\)-greedy, we consider finite action space, while the state space can be infinite.

**Definition 6 (Linear MDP [Jin et al., 2020b]).** An MDP is called linear MDP if its transition function admit the following form. \(P_h(s' \mid s, a) = \langle \phi_h(s, a), \mu_h(s') \rangle\) for some known function \(\phi_h : S \times A \rightarrow \mathbb{R}^d\) and unknown function \(\mu_h : S \rightarrow \mathbb{R}^d\). \(R_h(s,a) = \langle \phi_h(s, a), \theta_h \rangle\) for unknown parameters \(\theta_h\). Without loss of generality, we assume \(\|\phi_h(s, a)\| \leq 1\) for all \(s, a, h \in S \times A \times H\) and \(\max\{\|\mu_h(s)\|, \|\theta_h\|\} \leq \sqrt{d}\) for all \(s, h \in S \times [H]\).

An important property of Linear MDPs is that the value function also takes the linear form and the linear function class defined below satisfies Assumption 1.

**Proposition 3 (Proposition 2.3 [Jin et al., 2020b]).** For linear MDPs, we have for any policy \(\pi\),

\[
Q_{h,M}^\pi(s, a) = \langle \phi_h(s, a), w_{h,M}^\pi \rangle,
\]

where \(w_{h,M} = \theta_{h,M} + \int_S V_{h+1,M}^\pi(s')\mu_h(s')ds' \in \mathbb{R}^d\). Therefore, we only need to consider \(F_h = \{s, a \mapsto \langle \phi_h(s, a), w \rangle : w \in \mathbb{R}^d, \|w\| \leq 2\sqrt{d}\}\).

Now we are ready to define a diverse set of MDPs for the linear MDP case.

\[^1\text{Note that we consider non-negative measure } \mu_h.\]
We found in the experiments that the subset of tasks that leads to more spread spectrum coincidences we want to point out the intrinsic connection between the two settings: our algorithm, instead of which lower bounds the multitask myopic exploration gap. Combined with Theorem 1, we have a Theorem 2.

This manner is similar to the setup in linear MDPs. We have shown that to achieve diversity for linear MDPs, one important property is to have a full rank covariance matrix of the embeddings at each step linear mapping is applied to generate the final output (Bhateja et al., 2023; Hejna III & Sadigh, 2023). A naive solution is to request a diverse set as in Definition 7. Let \( \mathcal{M} \) to be a diverse set as in Definition 7. Suppose Assumption 2 holds and \( \beta \leq b_1/2 \), then we have for any \( f \in \mathcal{F}_\beta \), \( \alpha(f, \mathcal{F}, \mathcal{M}) = \Omega(\sqrt{\beta^2 b_1^2/|\mathcal{A}||\mathcal{M}|H}) \) by setting \( \epsilon_h = 1/(h+1) \).

放松覆盖假设。虽然特征覆盖假设（Assumption 2）对我们的证明来说是方便的，因为它保证了任何 \( \beta \)-最优策略（与 \( \beta \leq b_1/2 \) ）至少有 \( b_1/2 \) 的概率，以达到其目标状态，这可能不适用于表格 MDP。直观上，没有这个假设，一个 \( \beta \)-最优策略可以是任意的，而且我们可以有最多 \( S \) 个这样的政策在总和导致的累积误差中，这意味着 

6 Implications of Diversity in Deep RL

Though this is a paper focusing on the theoretical justification, we add some preliminary discussion on what diversity means in Deep RL. Thus far, we have provided concrete examples for diverse task set in tabular and linear MDPs with lower bounded Multitask MEG. It is often the case that in Deep RL, a pretrained feature extractor is used to generate embeddings for Q-function value and then a linear mapping is applied to generate the final output (Bhateja et al., 2023; Hejna III & Sadigh, 2023). This manner is similar to the setup in linear MDPs. We have shown that to achieve diversity for linear MDPs, one important property is to have a full rank covariance matrix of the embeddings at each step \( h \) if the optimal policy is executed (Lemma 1). In this section, we conduct simple simulation studies on BipedalWalker (Portelas et al., 2020), a robotic control environment, to verify that whether a more spread spectrum of the covariance matrix of the embeddings would lead to better sample efficiency.

We found in the experiments that the subset of tasks that lead to more spread spectrum coincidences with the task selection of automatic curriculum learning, which has been empirically shown to learn more sample efficiently. Due to the page limit we provide a high-level summary of the simulation study and the readers can find full details in Appendix I.

Experiment setup. The learning agent is embodied into a bipedal walker whose motors are controlled by continuous actions of torques. The objective of the agent is to move forward as far as possible,
while crossing stumps with varying heights at regular intervals. An environment or task, denoted as \( M_{p,q} \), is controlled by a parameter vector \((p, q)\), where \( p \) and \( q \) denote the heights of the stumps and the spacings between the stumps, respectively. Intuitively, challenging environments have higher and denser stumps. The agent is trained by Proximal Policy Optimization (PPO) (Schulman et al., 2017) with a standard actor-critic framework (Konda & Tsitsiklis, 1999) and with Boltzmann exploration that regularizes entropy. Detailed training setup can be found in Appendix I.

**Proper level of heights leads to more spread spectrum.** We evaluate the extracted feature at the end of the training generated by near-optimal policies on 100 tasks with different parameter vectors \((p, q)\). We then compute the covariance matrix of the features for each task, whose spectrum are shown in Figure 2(a). We observe that the eigenvalues can be 10 times higher for environments with an appropriate height (1.0-2.3), compared to extremely high and low heights, while they are roughly the same at different levels of spacings. This indicates that choosing an appropriate height is the key to properly scheduling tasks.

**Coincidence with automatic curriculum learning.** In fact, the task selection coincidences with the tasks selected by the state-of-the-art Automatic Curriculum Learning (ACL). We investigate the curricula generated by ALP-GMM (Portelas et al., 2020), a well-established curriculum learning algorithm, for training an agent in the BipedalWalker environment for 20 million timesteps. Figure 2(b) gives the density plots of the ACL task sampler during the training process, which shows a significant preference over heights in the middle range, with little preference over spacing. Since ACL has been shown to significantly improve the learning performance in BipedalWalker, this is a strong evidence that the diversity notation discussed in this paper truly leads to a better sample complexity even when Deep RL is employed.

![Figure 2](image_url)

Figure 2: (a) Boxplot of the log-scaled eigenvalues of sample covariance matrices of the trained embeddings generated by the near-optimal policies for different environments. (b) Task preference of automatically generated curriculum at 5M and 10M training steps respectively. The red regions are the regions where a task has a higher probability to be sampled.

7 DISCUSSIONS

In this paper, we propose a new perspective of understanding the sample efficiency of myopic exploration design through diverse multitask learning. We show that by learning a diverse set of tasks, multitask RL algorithm with myopic exploration design can be sample-efficient. This paper is a promising first step towards understanding the exploration benefits of MTRL.

**Towards diversity for general function classes.** Despite the rich discussion on explicit form of diversity set for tabular and linear MDP cases, how to achieve diversity for any general function class is an open problem. Recalling our proof for the Linear MDP case, a sufficient condition is to include a set of MDPs for each step \( h \), such that the state distribution generated by their optimal policies satisfy the concentrability assumptions. In other words, any MDP with positive reward only at the step \( h + 1 \) can be offline-learned through the dataset collected by these optimal policies. The diversity for general function classes poses the question on the number of tasks it takes to have sufficient coverage at the each step. We give a more detailed discussion of this topic in Appendix H.

**Improving sample-complexity bound.** Our sample complexity bound can be sub-optimal. For instance, Theorem 1 specialized to the tabular case has an upper sample complexity bound of \(|\mathcal{M}|^2S^3H^5A^2/\beta^2\), and the current optimal bound is \(|\mathcal{M}|SA/\beta^2\) if tasks are learned independently. We conjecture that this gap may originate from two factors. First, the nature of the myopic exploration makes it less efficient because the exploration are conducted in a layered manner. Second, our algorithm collects trajectories for every MDP with the mixture of all the policy in each round, which may be improved if a curriculum is prior known.

A RELATED WORKS

Multitask RL. Many recent theoretical works have contributed to understanding the benefits of MTRL (Agarwal et al., 2022; Brunskill & Li, 2013; Calandriello et al., 2014; Cheng et al., 2022; Lu et al., 2021; Uehara et al., 2021; Yang et al., 2022a; Zhang & Wang, 2021) by exploiting the shared structures across tasks. An earlier line of works (Brunskill & Li, 2013) assumes that tasks are clustered and the algorithm adaptively learns the identity of each task, which allows it to pool observations. For linear Markov Decision Process (MDP) settings (Jin et al., 2020b), Lu et al. (Lu et al., 2021) shows a bound on the sub-optimality of the learned policy by assuming a full-rank least-square value iteration weight matrix from source tasks. Agarwal et al. (Agarwal et al., 2022) makes a different assumption that the target transition probability is a linear combination of the source ones, and the feature extractor is shared by all the tasks. Our work differs from all these works as we focus on the reduced complexity of exploration design.

Curriculum learning. Curriculum learning refers to adaptively selecting tasks in a specific order to improve the learning performance (Bengio et al., 2009) under a multitask learning setting. Numerous studies have demonstrated improved performance in different applications (Jiang et al., 2015; Pentina et al., 2015; Graves et al., 2017; Wang et al., 2021). However, theoretical understanding of curriculum learning remains limited. Xu & Tewari (2022) study the statistical benefits of curriculum learning under Supervised Learning setting. For RL, Li et al. (Li et al., 2022b) makes a first step towards the understanding of sample complexity gains of curriculum learning without an explicit exploration bonus, which is a similar statement as we make in this paper. However, their results are under strong assumptions, such as prior knowledge on the curriculum and a specific contextual RL setting with Lipschitz reward functions. This work can be seen as a more comprehensive framework of such benefits, where we discuss general MDPs with function approximation.

Myopic exploration. Myopic exploration, characterized by its ease of implementation and effectiveness in many problems (Kalashnikov et al., 2018; Mnih et al., 2015), is the most commonly used exploration strategy. Many theory works (Dabney et al., 2020; Dann et al., 2022; Liu & Brunskill, 2018; Simchowitz & Foster, 2020) have discussed the conditions, under which myopic exploration is efficient. However, all these studies consider a single MDP and require strong conditions on the underlying environment. Our paper closely follows Dann et al. (Dann et al., 2022) where they define Myopic Exploration Gap. An MDP with low Myopic Exploration Gap can be efficiently learned by exploration exploration.

B A FORMAL DISCUSSION ON CURRICULUM LEARNING

We formally discuss that how our theory could provide a potential explanation on the success of curriculum learning in RL (Narvekar et al., 2020). Although Algorithm [1] does not explicitly implement curriculum learning by ordering tasks, we argue that if any curriculum learn leads to polynomial sample complexity $C$, then Algorithm [1] has $|\mathcal{M}|^2C$ sample complexity. We denote a curricula by $((M_i, T_i))_{i=1}^T$ and an online algorithm that learns through the curricula interacts with $M_i$ for $T_i$ rounds by rolling out trajectories with the estimated optimal policy of $M_{i-1}$ with epsilon greedy. This curricula is implicitly included in Algorithm [1] with $|\mathcal{M}| \sum_i T_i$ rounds. To see this, let us say in phase $i$, the algorithm has mastered all tasks $M_i, \ldots, M_{i-1}$. Then by running Algorithm [1] $|\mathcal{M}|^2T_i$ rounds, we will roll out $T_i$ trajectories on $M_i$ using the exploratory policy from $M_{i-1}$ on average, which reflects the schedules from curricula. This means that the sample-complexity of Algorithm [1] provides an upper bound on the sample complexity of underlying optimal curricula and in this way our theory provides some insights on the success of the curriculum learning.

C COMPARING SINGLE-TASK MEG AND MULTITASK MEG

Proposition [1]. Let $\mathcal{M}$ be any set of MDPs and $\mathcal{F}$ be any function class. We have that $\alpha(f_M, \mathcal{M}, \mathcal{F}) \geq \alpha(f_M, \{M_i\}, \mathcal{F})/\sqrt{|\mathcal{M}|}$ for all $f \in (\mathcal{F} \otimes |\mathcal{M}|)$ and $M \in \mathcal{M}$.
The above procedure will end in $O\left(\dfrac{1}{\delta} \log\left(\dfrac{H}{\delta}\right)\right)$ episodes and with a probability at least $1 - \delta$, $\pi_H$ is the optimal policy for $M$.

Proof. We construct the sequence in the following manner. Let the optimal policy for an MDP $M$ be $\pi_M^*$. Let the trajectory induced by $\pi_M^*$ be $\{s_0, a_0, \ldots, s_H, a_H\}$. The MDP $M$ receives a positive reward only when it reaches $s_H^*$. Without loss of generality, we assume that $M$ is initialized at a fixed state $s_0$. We choose $M_n$ such that $R_{M_n}(s, a) = 1(P_{M_n}(s, a) = s^*_i)$. Furthermore, we set $P_{M_n}(s^*_i | s^*_i, a) = 1 \forall a \in \mathcal{A}$ and $P_{M_n} = P_M$ otherwise.

This ensures that any policy that reaches $s^*_i$ on the $i$'th step is an optimal policy.

We first provide an upper bound on the expected number of episodes for finding an optimal policy using the above algorithm for $M_i$. Fix $2 \leq i \leq H$. Let $\epsilon = \frac{1}{i}$. Define $k = |\mathcal{A}|$. Then

Then the probability for reaching optimal reward for $M_i$ is less than or equal to $$(1 - \epsilon)^{-1} \left(\dfrac{1}{k^i}\right)$$

So the expected number of episodes to reach this optimal reward (and thus find an optimal policy) is

$$\dfrac{1}{(1 - \epsilon)^{-1} \left(\dfrac{1}{k^i}\right)} = (i - 1)k(\dfrac{i}{i - 1})^i \leq 4k(i - 1)$$

D EFFICIENT MYOPIC EXPLORATION FOR DETERMINISTIC MDP WITH KNOWN CURRICULUM

In light of the intrinsic connection between Algorithm 1 and curriculum learning. We present an interesting results for curriculum learning showing that any deterministic MDP can be efficiently learned through myopic exploration when a proper curriculum is given.

**Proposition 4.** For any deterministic MDP $M$, with sparse reward, there exists a sequence of deterministic MDPs $M_1, M_2, \ldots, M_H$, such that the following learning process returns an optimal policy for $M$:

1. Initialize $\pi_0$ by a random policy.
2. For $t = 1, \ldots, n$, follow $\pi_{t-1}$ with an $\epsilon$-greedy exploration to collect $4At \log(H/\delta)$ trajectories denoted by $D_t$. Compute the optimal policy $\pi_t$ from the model learned by $D_t$.
3. Output $\pi_H$.

The above procedure will end in $O(AH^2 \log(H/\delta))$ episodes and with a probability at least $1 - \delta$, $\pi_H$ is the optimal policy for $M$.

Proof. The proof is straightforward from the definition of multitask MEG. For any MDP $M$ and any $f \in \mathcal{F}^{|\mathcal{M}|}$, $\alpha(f, \{M\}, \mathcal{F})$ is the value to the following optimization problem

$$\sup_{f \in \mathcal{F}, c \geq 1} \frac{1}{\sqrt{c}} (V_{\pi_f} - V_{\pi_f}^{fM})$$

s.t. for all $f' \in \mathcal{F}$ and $h \in [H]$,

$$\mathbb{E}^M_{\pi_f}[(\mathcal{E}_{\pi_f}^M f')(s, a)] \leq c \mathbb{E}^M_{\pi_f}[(\mathcal{E}_{\pi_f}^M f')(s, a)]^2$$

$$\mathbb{E}^M_{\pi_f}[(\mathcal{E}_{\pi'}^M f')(s, a)] \leq c \mathbb{E}^M_{\pi_f}[(\mathcal{E}_{\pi'}^M f')(s, a)]^2.$$ 

By choosing $c$ in Definition 3 by $c|\mathcal{M}|$, and $f'$ by the same $f'$ that attains the maximization in Single-task MEG, we have $\alpha(f, \{M\}, \mathcal{F}) \geq \alpha(f, \{M\}, \mathcal{F}) / \sqrt{|\mathcal{M}|}$.
since \( i \geq 2 \) and \( (\frac{i}{i-1})^i \) is decreasing. By Chebyshev’s inequality, a successful visit can be found in \( 4k(i - 1) \log(H/\delta) \) with a probability at least \( 1 - \delta/H \).

The expected total number of episodes for the all the MDP’s is therefore

\[
\sum_{j=2}^{H} 4k(j - 1) \log(H/\delta) \leq \frac{H}{2} (4kH) \log(H/\delta)
\]

which is \( O(kH^2 \log(H/\delta)) \).

\[\square\]

### E Generic Upper Bound for Sample Complexity

In this section, we prove the generic upper bound on sample complexity in Theorem[1]. We first prove Lemma[2], which holds under the same condition of Theorem[1].

**Lemma 2.** Consider a multitask RL problem with MDP set \( \mathcal{M} \) and value function class \( \mathcal{F} \) such that \( \mathcal{M} \) is \((\hat{\alpha}, \hat{\beta})\)-diverse. Then Algorithm [1] running \( T \) rounds with exploration function expl satisfies that with a probability at least \( 1 - \delta \), the total number of rounds, where there exists an MDP \( M \), such that \( \hat{\pi}_t,M \) is \( \beta \)-suboptimal for \( M \), can be upper bounded by

\[
\mathcal{O}\left( |\mathcal{M}| H^2 d_{BE}(\mathcal{F}, \Pi_{\mathcal{F}}, 1/\sqrt{T}) \frac{\ln(\hat{\beta})}{\hat{\alpha}(\beta)} \frac{\ln\left( N_{\mathcal{F}}(T^{-1}) \ln(T) \right)}{\delta} \right),
\]

where \( \dim_{BE}(\mathcal{F}, \Pi_{\mathcal{F}}, 1/\sqrt{T}) \) is the Bellman-Eluder dimension of class \( \mathcal{F} \) and \( N_{\mathcal{F}}(\rho) = \sum_{h=1}^{H-1} N_{\mathcal{F}_h}(\rho) N_{\mathcal{F}_{h+1}}(\rho) \).

**Proof.** Let us partition \( \mathcal{F}_{\beta} \) into \( \mathcal{F}_{\beta} = \{ \mathcal{F}_{M,i} \}_{M \in \mathcal{M}, i \in [t_{\max}]} \) such that

\[
\mathcal{F}_{M,i} := \{ f \in \mathcal{F}_{\beta} : c(f, M, \mathcal{F}) \in [\epsilon^{i-1}, \epsilon^i] \} \text{ and } M(f, M, \mathcal{F}) = M.
\]

Furthermore, denote \( (\hat{f}_{t,M})_{M \in \mathcal{M}} \) by \( \hat{f}_t \). We define \( K_{M,i,t} = \{ \tau \in [t], \hat{f}_\tau \in \mathcal{F}_{M,i} \} \). The proof in [Dann et al. 2022] can be seen as bounding the sum of \( K_{M,i,t} \) for a specific \( M \), while apply the same bound for each \( M \), which leads to an extra \( |\mathcal{M}| \) factor.

**Lemma 3.** Under the same condition in Theorem[1] and the above definition, we have

\[
|K_{M,i,t}| \leq \mathcal{O}\left( H^2 d_{BE}(\mathcal{F}, \Pi_{\mathcal{F}}, 1/\sqrt{T}) \frac{\ln\left( N_{\mathcal{F}}(1/T) \ln(T) \right)}{\delta} \right).
\]

**Proof.** In the following proof, we fix an MDP \( M \) and without further specification, the policies or rewards are with respect to the specific \( M \). We study all the steps \( t \in K_{M,i,T} \).

For each \( t \in K_{M,i,T} \),

1. Recall that \( \hat{\pi}_t \) is the mixture of exploration policy for all the MDPs: \( \text{Mixture}(\{\text{expl}(\hat{\pi}_{t,M'})\}_{M' \in \mathcal{M}}) \);

2. Define \( \hat{\pi}'_t \) as the improved policy that attains the maximum in the multitask myopic exploration gap for \( \hat{f}_t \) in Definition[3].

Note that \( \hat{\pi}'_t \) is a policy for \( M \) since \( t \in K_{M,i,t} \). A key step in our proof is to upper bound the difference between the value of the current policy and the value of \( \hat{\pi}'_t \). By Lemma[4] The total difference in return between the greedy policies and the improved policies can be bounded by

\[
\sum_{t \in K_{M,i,T}} (V_{1,M}(s_1) - V_{\hat{\pi}_t,M}(s_1)) \leq \sum_{t \in K_{M,i,T}} \sum_{h=1}^{H} \mathbb{E}_{\hat{\pi}'_t,M} [\epsilon_{h}^{M}(\hat{f}_{t,M})(s_h, a_h)] - \sum_{t \in K_{M,i,T}} \sum_{h=1}^{H} \mathbb{E}_{\pi}' [\epsilon_{h}^{M}(\hat{f}_{t,M})(s_h, a_h)],
\]

where the expectation is taken over the randomness of the trajectory sampled for MDP \( M \).

(3)
Under the completeness assumption in Assumption[1] by Lemma[5] we show that with a probability $1 - \delta$ for all $(h, t) \in [H] \times [T]$,  
\[
\sum_{\tau=1}^{t-1} \mathbb{E}_{\pi_t}^M \left[ (c_h f_{t,M}) (s_h, a_h) \right]^2 \leq 3 \frac{T-1}{T} + 176 \ln \frac{6N_F (1/T) \ln(2t)}{\delta}.
\]

We consider only the event, where this condition holds. Since $c(\hat{f}_t, M, F) \leq \epsilon_t$ for all $t \in K_{M,i,T}$, by Definition[3] we bound  
\[
\sum_{\tau \in K_{M,i,T}} \mathbb{E}_{\pi_t}^M \left[ (c_h f_{t,M}) (s_h, a_h) \right]^2 
\leq e^i \sum_{\tau \in [t-1]} \mathbb{E}_{\pi_t}^M \left[ (c_h f_{t,M}) (s_h, a_h) \right]^2 
\leq e^i \sum_{\tau \in [t-1]} \mathbb{E}_{\pi_t}^M \left[ (c_h f_{t,M}) (s_h, a_h) \right]^2 
\leq 179 e^i \frac{6N_F (1/T) \ln(2t)}{\delta}.
\]

Combined with the distributional Eluder dimension machinery in Lemma[7] this implies that  
\[
\sum_{t \in K_{M,i,T}} \mathbb{E}_{\pi_t}^M \left[ (c_h f_{t,M}) (s_h, a_h) \right] \leq O \left( \sqrt{e^i \epsilon_d BE (\mathcal{F}, \Pi_F, 1/\sqrt{T}) \ln \frac{N_F (1/T) \ln(T)}{\delta} |K_{M,i,T}| + \min \left\{|K_{M,i,T}|, \epsilon_d BE (\mathcal{F}, \Pi_F, 1/\sqrt{T})\right\} \right),
\]

Note that we can derive the same upper-bound for  
\[
\sum_{t \in K_{M,i,T}} \mathbb{E}_{\pi_t}^M \left[ (c_h f_{t,M}) (s_h, a_h) \right].
\]

Then plugging the above two bounds into Equation[3], we obtain  
\[
\sum_{t \in K_{M,i,T}} (V_{1,M}^\pi(s_1) - V_{1,M}^{\hat{\pi}_M}(s_1)) \leq O \left( \sqrt{e^i H^2 \epsilon_d BE (\mathcal{F}, \Pi_F, 1/\sqrt{T}) \ln \frac{N_F (1/T) \ln(T)}{\delta} |K_{M,i,T}| + H \epsilon (\mathcal{F}_i) \right).
\]

By the definition of myopic exploration gap, we lower bound the LHS by  
\[
\sum_{t \in K_{M,i,T}} (V_{1,M}^\pi(s_1) - V_{1,M}^{\hat{\pi}_M}(s_1)) \geq |K_{M,i,T}| \sqrt{e^i - 1} \alpha \beta.
\]

Combining both bounds and rearranging yields  
\[
|K_{M,i,T}| \leq O \left( \frac{H^2 \epsilon_d BE (\mathcal{F}, \Pi_F, 1/\sqrt{T}) \ln \frac{N_F (1/T) \ln(T)}{\delta}}{\alpha \beta^2} \right).
\]

Summing over $M \in \mathcal{M}$ and $i \leq i_{max} < \ln \tilde{\epsilon}(\beta)$, we conclude Lemma[2].

To convert Lemma[2] into a sample complexity bound in Theorem[1] we show that for all $M$,  
\[
\hat{\pi}_M = \text{Mixture}(\{\pi_{f_{t,M}}\}) \text{ is } \beta\text{-optimal for } M.
\]

\[
\max_{\pi \pi_{1,M} - V_{1,M}^{\hat{\pi}_M}(s_1) = O \left( \frac{\beta |M| H^2 \epsilon_d BE (\mathcal{F}, \Pi_F, 1/\sqrt{T}) \ln \tilde{\epsilon}(\beta) \ln \left( \frac{N_F (T^2) \ln T}{\delta} \right)}{T} \right).}
\]

17
To have the above suboptimality controlled at the level $\beta$, we will need
\[
O \left( \frac{\beta |M| H^2 d_{BE}(F, \Pi_F, 1/\sqrt{T}) \ln (\hat{c}(\beta))}{\alpha(\beta)^2 T \ln \left( \frac{N_{\beta}(T-1) \ln T}{\delta} \right)} \right) = \beta.
\]

Assume that $d_{BE}(F, \Pi_F, \rho) = O(d_{BE}^F \log (1/\rho))$ and $\ln (N'(F)(\rho)) = O(d_{BE}^{\cover} \log (1/\rho))$ by ignoring other factors, which holds for most regular function classes including tabular and linear classes [Russo & Van Roy 2013], we have
\[
T = O \left( \frac{|M| H^2 d_{BE}^F \ln (\hat{c}(\beta))}{\alpha(\beta)^2 \ln \left( \frac{1}{\delta} \ln (1/\rho) \right)} \right),
\]
where $\rho^{-1} = O \left( \frac{|M| H^2 d_{BE}^F \ln (\hat{c}(\beta))}{\alpha(\beta)^2} \ln (1/\rho) \right)$. The final bound has an extra $|M|$ dependence because we execute a policy for each MDP in a round.

E.1 TECHNICAL LEMMAS

**Lemma 4 (Lemma 3 [Dann et al. 2022]).** For any MDP $M$, let $f = \{f_h\}_{h \in [H]}$ with $f_h : S \times A \mapsto \mathbb{R}$ and $\pi^f$ is the greedy policy of $f$. Then for any policy $\pi'$,
\[
V^t_{\pi'}(s_1) - V^t_{\pi'}(s_1) \leq \sum_{h=1}^{H} \mathbb{E}^{M}_{s_1} [(\mathcal{E}_h f)(s_h, a_h)] - \sum_{h=1}^{H} \mathbb{E}^{M}_{s_1} [(\mathcal{E}_h f)(s_h, a_h)].
\]

**Lemma 5 (Modified from Lemma 4 [Dann et al. 2022]).** Consider a sequence of policies $(\pi_t)_{t \in \mathbb{N}}$. At step $\tau$, we collect one episode using $\hat{\pi}_\tau$ and define $f_\tau$ as the fitted Q-learning estimator up to step $t$ over the function class $F = \{f\}_{h \in [H]}$. Let $\rho \in \mathbb{R}^+$ and $\delta \in (0, 1)$. If $F$ satisfies Assumption 1 then with a probability at least $1 - \delta$, for all $h \in [H]$ and $t \in \mathbb{N}$,
\[
\sum_{t=1}^{t-1} \mathbb{E}_{s_1}^{M} [(\mathcal{E}_h f_{\hat{\tau}})(s_h, a_h)]^2 \leq 3\rho t + 176 \ln \left( \frac{6 N'_{\rho}(\rho) \ln (2t)}{\delta} \right),
\]
where $N'_{\rho}(\rho) = \sum_{h=1}^{H} N_{F_h}(\rho) N_{F_{h+1}}(\rho)$ is the sum of $\ell_{\infty}$ covering number of $F_h \times F_{h+1}$ w.r.t. radius $\rho > 0$.

**Proof.** The only difference between our statement and the statement in [Dann et al. 2022] is that they consider $\hat{\pi}_\tau = \exp (f_\tau)$, while this statement holds for any data-collecting policy $\pi_\tau$. To show this, we go through the complete proof here.

Consider a fixed $t \in \mathbb{N}$, $h \in [H]$ and $f = \{f_h, f_{h+1}\}$ with $f_h \in F_h$, $f_{h+1} \in F_{h+1}$. Let $(x_{t,h}, a_{t,h}, r_{t,h})_{t \in \mathbb{N}, h \in [H]}$ be the collected trajectory in $[t]$. Then
\[
Y_{t,h}(f) = \left( f_h(x_{t,h}, a_{t,h}) - r_{t,h} - \max_{a'_{t,h}} f_{h+1}(x_{t,h+1}, a') \right)^2 - \left( (\mathcal{T}_h f_{h+1})(x_{t,h}, a_{t,h}) - r_{t,h} - \max_{a'_{t,h}} f_{h+1}(x_{t,h+1}, a') \right)^2
\]
\[
= (f_h(x_{t,h}, a_{t,h}) - (\mathcal{T}_h f_{h+1})(x_{t,h}, a_{t,h})) \times \left( f_h(x_{t,h}, a_{t,h}) + (\mathcal{T}_h f_{h+1})(x_{t,h}, a_{t,h}) - 2r_{t,h} - 2 \max_{a'_{t,h}} f_{h+1}(x_{t,h+1}, a') \right).
\]

Let $\mathcal{F}_t$ be the $\sigma$-algebra under which all the random variables in the first $t-1$ episodes are measurable. Note that $|Y_{t,h}(f)| \leq 4$ almost surely and the conditional expectation of $Y_{y,h}(f)$ can be written as
\[
\mathbb{E} [Y_{t,h}(f) | \mathcal{F}_t] = \mathbb{E} \mathbb{E} [Y_{t,h}(f) | \mathcal{F}_t, x_{t,h}, a_{t,h}] | \mathcal{F}_t] = \mathbb{E} \mathbb{E} [(f_h - \mathcal{T}_h f_{h+1})(x_h, a_h) | \mathcal{F}_t].
\]

The variance can be bounded by
\[
\text{Var} [Y_{t,h}(f) | \mathcal{F}_t] \leq \mathbb{E} [Y_{t,h}(f)^2 | \mathcal{F}_t] \leq 16 \mathbb{E} \left[ (f_h - \mathcal{T}_h f_{h+1})(x_h, a_h)^2 | \mathcal{F}_t \right] = 16 \mathbb{E} [Y_{t,h}(f) | \mathcal{F}_t],
\]
where we used the fact that $\|f_h(x_{t,h}, a_{t,h}) + (T_{h,f_h+1})(x_{t,h}, a_{t,h}) - 2r_{t,h} - 2\max_{a'} f_{h+1}(x_{h+1}, a')\| \leq 4$ almost surely. Applying Lemma 6 to the random variable $Y_{t,h}(f)$, we have that with probability at least $1 - \delta$, for all $t \in \mathbb{N}$,

$$
\sum_{i=1}^{t} \mathbb{E}[Y_{i,h}(f) \mid \mathcal{F}_i] \leq 2A_t \left( \sqrt{\sum_{i=1}^{t} \text{Var}(Y_{i,h}(f) \mid \mathcal{F}_i) + 12A_t^2 + \sum_{i=1}^{t} Y_{i,h}(f)} \right)
$$

$$
\leq 8A_t \left( \sum_{i=1}^{t} \mathbb{E}[Y_{i,h}(f) \mid \mathcal{F}_i] + 12A_t^2 + \sum_{i=1}^{t} Y_{i,h}(f) \right)
$$

where $A_t = \sqrt{2\ln \ln(2t) + \ln(6/\delta)}$. Using AM-GM inequality and rearranging terms in the above we have

$$
\sum_{i=1}^{t} \mathbb{E}[Y_{i,h}(f) \mid \mathcal{F}_i] \leq 2 \sum_{i=1}^{t} Y_{i,h}(f) + 88A_t^2 \leq 2 \sum_{i=1}^{t} Y_{i,h}(f) + 176 \ln \frac{6\ln(2t)}{\delta}.
$$

Let $\mathcal{Z}_{\rho,h}$ be a $\rho$-cover of $\mathcal{F}_h \times \mathcal{F}_{h+1}$. Now taking a union bound over all $\phi_h \in \mathcal{Z}_{\rho,h}$ and $h \in [H]$, we obtain that with probability at least $1 - \delta$ for all $\phi_h$ and $h \in [H]$

$$
\sum_{i=1}^{t} \mathbb{E}[Y_{i,h}(\phi_h) \mid \mathcal{F}_i] \leq 2 \sum_{i=1}^{t} Y_{i,h}(\phi_h) + 176 \ln \frac{6N_{\mathcal{F}}(\rho) \ln(2t)}{\delta}.
$$

This implies that with probability at least $1 - \delta$ for all $f = \{f_h, f_{h+1}\} \in \mathcal{F}_h \times \mathcal{F}_{h+1}$ and $h \in [H]$

$$
\sum_{i=1}^{t} \mathbb{E}[Y_{i,h}(f) \mid \mathcal{F}_i] \leq 2 \sum_{i=1}^{t} Y_{i,h}(f) + 3\rho(t-1) + 176 \ln \frac{6N_{\mathcal{F}}(\rho) \ln(2t)}{\delta}.
$$

Let $\hat{f}_{t,h}$ be the $h$-th component of the function $\hat{f}_t$. The above inequality holds in particular for $f = \{\hat{f}_{t,h}, \hat{f}_{t,h+1}\}$ for all $t \in \mathbb{N}$. Finally, we have

$$
\sum_{i=1}^{t-1} Y_{i,h}(\hat{f}_t) = \sum_{i=1}^{t-1} \left( \hat{f}_{t,h}(s_{i,h}, a_{i,h}) - r_{i,h} - \max_{a'} \hat{f}_{t,h+1}(s_{i,h+1}, a') \right)^2
$$

$$
- \sum_{i=1}^{t-1} \left( (T_h \hat{f}_{t,h+1})(s_{i,h}, a_{i,h}) - r_{i,h} - \max_{a'} \hat{f}_{t,h+1}(s_{i,h+1}, a') \right)^2
$$

$$
= \min_{f' \in \mathcal{F}_h} \sum_{i=1}^{t-1} \left( f'(s_{i,h}, a_{i,h}) - r_{i,h} - \max_{a'} \hat{f}_{t,h+1}(s_{i,h+1}, a') \right)^2
$$

$$
\leq 0,
$$

where the last inequality follows from the completeness in Assumption [1].

\[ \square \]

**Lemma 6** (Time-Uniform Freedman Inequality). Suppose $\{X_t\}_{t=1}^{\infty}$ is a martingale difference sequence with $|X_t| \leq b$. Let

$$
\text{Var}_t(X_t) = \text{Var}(X_t \mid X_1, \cdots, X_{t-1}).
$$

Let $V_t = \sum_{\ell=1}^{t} \text{Var}_\ell(X_\ell)$ be the sum of conditional variances of $X_t$. Then we have that for any $\delta' \in (0, 1)$ and $t \in \mathbb{N}$

$$
P\left( \sum_{\ell=1}^{t} X_\ell > 2\sqrt{V_t A_t + 3bA_t^2} \right) \leq \delta'
$$

where $A_t = \sqrt{2\ln \ln(2(\max(V_t/b^2, 1))) + \ln(6/\delta')}$. 

19
Lemma 7 (Lemma 41 [In et al., 2021a]). Given a function class \( \Phi \) defined on \( X \) with \( |\phi(x)| \leq C \) for all \((\phi,x) \in \Phi \times X\) and a family of probability measures \( \Pi \) over \( X \). Suppose sequences \( \{\phi_i\}_{i \in [K]} \subseteq \Phi \) and \( \{\mu_i\}_{i \in [K]} \subseteq \Pi \) satisfy for all \( k \in [K] \) that \( \sum_{i=1}^{k-1}(\mathbb{E}_{\mu_i}[\phi_k])^2 \leq \beta \). Then for all \( k \in [K] \) and \( w > 0 \),
\[
\sum_{t=1}^{k} |\mathbb{E}_{\mu_t}[\phi_t]| \leq O\left(\sqrt{\dim_{DE}(\Phi, \Pi, \omega)} \beta k + \min \{k, \dim_{DE}(\Phi, \Pi, \omega)\} C + k \omega \right).
\]

**Proof of Theorem 6** Denote \( B = \Theta\left( |\mathcal{M}| \frac{H^2d_{BE}}{\alpha(\beta)^2} \ln \frac{N_F(T)^{-1}}{\beta} \right) \). The following Corollary transform Lemma 2 to Theorem 1, whose proof directly follows by taking \( T = B / \beta \). Since at most \( B \) rounds are suboptimal according to Lemma 2, the mixing of all \( T \) policies are \( \beta \)-optimal. This leads to a sample complexity
\[
C(\hat{\alpha}, \hat{\epsilon}) = \Theta\left( |\mathcal{M}| \frac{H^2d_{BE}}{\alpha(\beta)^2} \ln \frac{N_F(T^{-1})}{\beta} \right).
\]

**F Omitted Proofs for Case Studies**

### F.1 Linear MDP Case

Note that in this section, we use \( \mathbb{E}_{\pi} \) for the expectation over transition w.r.t a policy \( \pi \).

**Lemma 8.** Let \( F \) be the function class in Proposition 3. For any policy \( \pi \) such that \( \lambda_{min}(\Phi_h) \geq \lambda \), then for any policy \( \pi' \) and \( f' \in F \), \( \mathbb{E}_{\pi'}[(\mathcal{E}^2_h f')(s_h, a_h)] \leq \mathbb{E}_{\pi}[(\mathcal{E}^2_h f')(s_h, a_h)] / \lambda \).

**Proof.** Recall that \( \Phi_h^\pi := \mathbb{E}_{\pi} \phi_h(s_h, a_h) \phi_h(s_h, a_h)^\top \).

We derive the Bellman error term using the fact that \( f' \) is a linear function and the transitions admit the linear function as well. For any policy \( \pi \), we have
\[
\mathbb{E}_{\pi}[ (\mathcal{E}^2_h f')(s_h, a_h) ]
= \frac{\mathbb{E}_\pi}{\mathbb{E}_\pi} \left( f_h'(s_h, a_h) - \phi_h(s_h, a_h)^\top \theta_h - \max_{\alpha'} \mathbb{E}_{s_{h+1}}[ f_h'(s_{h+1}, a') | s_h, a_h ] \right)^2
= \frac{\mathbb{E}_\pi}{\mathbb{E}_\pi} \left( \phi_h(s_h, a_h)^\top w_h - \phi_h(s_h, a_h)^\top \theta_h - \max_{\alpha'} \mathbb{E}_{s_{h+1}}[ \phi_h(s_{h+1}, a')^\top w_{h+1} | s_h, a_h ] \right)^2
= \frac{\mathbb{E}_\pi}{\mathbb{E}_\pi} \left( \phi_h(s_h, a_h)^\top w_h - \phi_h(s_h, a_h)^\top \theta_h - \phi_h(s_h, a_h)^\top \int s' \phi_h(s', \pi_h'(s')^\top w_{h+1} \mu_h(s') ds' \right)^2
= \frac{\mathbb{E}_\pi}{\mathbb{E}_\pi} \left( \phi_h(s_h, a_h)^\top (w_h - \theta_h - w_{h+1}) \right)^2
= (w_h - \theta_h - w_{h+1})^\top \mathbb{E}_\pi \phi_h(s_h, a_h) \phi_h(s_h, a_h)^\top (w_h - \theta_h - w_{h+1})
\]
where \( w_{h+1} = \int s' \phi_h(s', \pi_h'(s'))^\top w_{h+1} \mu_h(s') ds' \). Since by the assumption in Definition 6 that \( \|\phi_h(s,a)\| \leq 1 \) for any \( s, a \), we have \( \Phi_h^\pi \prec I \). The result follow by the condition that \( \lambda_{min}(\Phi_h^\pi) \geq \lambda \).

**Lemma 1** Fix a step \( h \). Let \( \{M_{i,h}\}_{i \in [d]} \) be the \( d \) MDPs such that \( \theta_{h,M_{i,h}} = e_i \) as in Definition 6. Let \( \{\pi_{i,h}\}_{i \in [d]} \) be \( d \) policies such that \( \pi_i \) is a \( \beta \)-optimal policy for \( M_{i,h} \) with \( \beta < b_1/2 \). Let \( \pi = \text{Mixture}\{\exp(\pi_i)\}_{i \in [d]} \). Then for any \( \nu \in \mathbb{S}^{d-1} \), we have \( \lambda_{min}(\Phi_{h+1}) \geq \nu_{h+1} \prod_{i=1}^{d-1} (1 - \nu_{h+1}) b_i^2 / (2dA) \).

**Proof.** Let \( \pi \) be any stationary policy and recall that \( \Pi \) is the set of all the stationary policies. We denote \( A_h^\pi(s') \sim \pi_h(s') \) by the random variable for the action sampled at the step \( h \) using policy \( \pi \) given the state is \( s' \). Let \( \phi_h^\pi := \mathbb{E}_{\pi} \phi_h(s_h, a_h) \).
We further define
\[ a_{h+1}^\nu(s) := \arg\max_{a \in A} [\nu^\top \phi_{h+1}(s, a) \phi_{h+1}(s, a)^\top \nu]. \]

Lower bound the following quadratic term for any unit vector \( \nu \in \mathbb{R}^d \),
\[
\max_{\pi \in \Pi} \nu^\top \Phi_{h+1}^\nu \pi \\
= \max_{\pi \in \Pi} \mathbb{E}_\pi \left[ \int_{s'} \nu^\top \phi_{h+1}(s', A^\pi_{h+1}(s')) \phi_{h+1}(s', A^\pi_{h+1}(s'))^\top \nu \mu_h(s') ds' \right] \\
= \max_{\pi} \mathbb{E}_\pi [\phi_h(s_h, a_h)^\top] \left( \int_{s'} \nu^\top \phi_{h+1}(s', a^*_{h+1}(s')) \phi_{h+1}(s', a^*_{h+1}(s'))^\top \nu \mu_h(s') ds' \right) \\
= \max_{\pi} (\phi^\top h) w_{h+1}^\nu.
\]

where we let \( w_{h+1}^\nu := \int_{s'} \nu^\top \phi_{h+1}(s', a^*_{h+1}(s')) \phi_{h+1}(s', a^*_{h+1}(s'))^\top \nu \mu_h(s') ds' \).

By Assumption 2 we have \( \max_{\pi \in \Pi} \mathbb{E}_\pi [\phi_h(s_h, a_h)^\top] w_{h+1}^\nu \geq b_2^2 \).

For the mixture policy \( \tilde{\pi} \) defined in our lemma,
\[
\nu^\top \Phi_{h+1}^\nu \tilde{\pi} = \frac{1}{d} \sum_{i=1}^d \mathbb{E}_{\text{expl}(\pi_i)} [\nu^\top \phi_{h+1}(s_h, a_h) \phi_{h+1}(s_h, a_h)^\top \nu] \\
\geq \frac{\epsilon_h \prod_{k=1}^{h-1} (1 - \epsilon_h)}{Ad} \sum_{i=1}^d (\phi^\top \pi_i) w_{h+1}^\nu. \tag{4}
\]

Since \( \pi_i \) is a \( b_1/2 \)-optimal policy for MDP \( M_{i,h} \) and again by Assumption 2 we have
\[
\theta_{h, M_{i,h}}^\nu \phi^\top \pi_i \geq \frac{1}{2} \max_{\pi} \theta_{h, M_{i,h}}^\nu \phi^\top h. \tag{5}
\]

For any vector \( \nu \in \mathbb{R}^d \), let \( [\nu]_i \) be the \( i \)-th dimension of the vector. Note that \( \theta_{h, M_{i,h}} = \epsilon_i \).

Combining the inequality (5) with (4), we have
\[
\nu^\top \Phi_{h+1}^\nu \tilde{\pi} = \frac{\epsilon_h \prod_{k=1}^{h-1} (1 - \epsilon_h)}{dA} \sum_{i=1}^d \sum_{j=1}^d (\phi^\top \pi_i) [w_{h+1}^\nu]_j \\
\geq \frac{\epsilon_h \prod_{k=1}^{h-1} (1 - \epsilon_h)}{dA} \sum_{i=1}^d (\phi^\top \pi_i) [w_{h+1}^\nu]_i \\
\geq \frac{\epsilon_h \prod_{k=1}^{h-1} (1 - \epsilon_h)}{dA} \max_{\pi} (\phi^\top \pi) [w_{h+1}^\nu]_i \\
\geq \frac{\epsilon_h \prod_{k=1}^{h-1} (1 - \epsilon_h)}{2dA} \max_{\pi} (\phi^\top \pi) w_{h+1}^\nu \\
\geq \frac{\epsilon_h \prod_{k=1}^{h-1} (1 - \epsilon_h) b_2^2}{2dA}.
\]

\( \Box \)

F.2 Proof of Theorem 2

Theorem 2. Consider \( \mathcal{M} \) defined in Definition 7 With Assumption 2 holding and \( \beta \leq b_1/2 \), for any \( f \in \mathcal{F}_\beta \), we have lower bound \( \alpha(f, \mathcal{F}, \mathcal{M}) \geq \sqrt{\epsilon h^2 \beta^2} \) by setting \( \epsilon_h = 1/h \).

Proof. Let \( h' \) be the smallest \( h \) such that there exists \( M_{i,h}, \pi^{f,M_{i,h}} \) is \( \beta \)-suboptimal. Let \( (s', h') \) be the index of the MDP that has the suboptimal policy. We show that \( M_{i,h'} \) has lower bounded myopic exploration gap.
By definition, $f$ is $\beta$-optimal for any MDP $M_{i,h'}$. By Lemma 1 letting $\bar{\pi} = \exp(f, \epsilon_{h'})$, we have

$$\nu^T \Phi^{h'}_{h'+1} \nu \geq \frac{\epsilon_{h'} \prod_{h''=1}^{h'-1} (1 - \epsilon_{h''}) b_1^2}{2A|\mathcal{M}|}.$$  

By Lemma 8 we have that the optimal value function $f^*$ for MDP $M_{i', h'}$ satisfies that for any $f'$

$$\mathbb{E}^M_{\pi^*} \left[ (\mathcal{E}^2 f') (s_h, a_h) \right] \leq \frac{2A|\mathcal{M}|}{\epsilon_{h'} \prod_{h''=1}^{h'-1} (1 - \epsilon_{h''}) b_1^2} \mathbb{E}^M_{\bar{\pi}} \left[ (\mathcal{E}^2 f') (s_h, a_h) \right].$$

Thus, by Definition 3 the myopic exploration gap for $f$ is lower bounded by

$$\beta \frac{1}{\sqrt{c}} = \beta \sqrt{\frac{\epsilon_{h'} \prod_{h''=1}^{h'-1} (1 - \epsilon_{h''}) b_1^2}{2A|\mathcal{M}|}} \geq \sqrt{\frac{\beta^2 b_1^2}{2A|\mathcal{M}| c^H}},$$

if we choose $\epsilon_{h} = 1/(h + 1)$.

### F.3 Linear Quadratic Regulator

To demonstrate the generalizability of the proposed framework, we introduce another interesting setting called Linear Quadratic Regulator (LQR). LQR takes continuous state space $\mathbb{R}^{d_a}$ and action space $\mathbb{R}^{d_u}$. In the LQR system, the state $s_h \in \mathbb{R}^{d_a}$ evolves according to the following transition:

$$s_{h+1} = A_h s_h + B_h a_h,$$

where $A_h \in \mathbb{R}^{d_a \times d_a}$, $B_h \in \mathbb{R}^{d_u \times d_a}$ are unknown system matrices that are shared by all the MDPs. We denote $s_h = (s_h, a_h)$ as the state-action vector. The reward function for an MDP $M$ takes a known quadratic form $r_{h,M}(s,a) = s^T R_{h,M} s + a^T R_{h,M} a$, where $R_{h,M} \in \mathbb{R}^{d_a \times d_a}$ and $R_{h,M} \in \mathbb{R}^{d_u \times d_u}$.

Note that LQR is more commonly studied for the infinite-horizon setting, where stabilizing the system is a primary concern of the problem. We consider the finite-horizon setting, which alleviates the difficulties on stabilization so that we can focus our discussion on exploration. Finite-horizon LQR also allows us to remain consistent notations with the rest of the paper. A related work (Simchowitz & Foster, 2020) states that naive exploration is optimal for online LQR with a condition that the system injects a random noise onto the state observation with a full rank covariance matrix $\Sigma > 0$. Though this is a common assumption in LQR literature, one may notice that the analog of this assumption in the tabular MDP is that any state and action pair has a non-zero probability of visiting any other state, which makes naive exploration sample-efficient trivially. In this section, we consider a deterministic system, where naive exploration does not perform well in general.

**Properties of LQR.** It can be shown that the optimal actions are linear transformations of the current state (Farjadnasab & Babazadeh, 2022; Li et al., 2022a). The optimal linear response is characterized by the discrete-time Riccati equation given by

$$P_{h,M} = A_h^T (P_{h+1,M} - P_{h+1,M} \bar{R}_{h+1,M}^{-1} B_h^T P_{h+1,M}) A_h + \bar{R}_{h+1,M},$$

where $\bar{R}_{h+1,M} = R_{h+1,M} + B_h^T P_{h+1,M} A_h$ and $P_{H+1} = 0$. Assume that the solution for the above equation is $\{P_{h,M}\}_{h\in[H+1]}$, then the optimal control actions takes the form

$$a_h = F_{h,M}^* s_h,$$

where $F_{h,M}^* = -(R_{h,M} + B_h^T P_{h,M} A_h)^{-1} B_h^T P_{h,M}^* A_h$.

and optimal value function takes the quadratic form: $V_{h,M}(s) = s^T P_{h,M} s$ and

$$Q_{h,M}(x) = x^T \begin{bmatrix} R_{h,M} + A_h^T P_{h+1,M} A_h & A_h^T P_{h+1,M} B_h \\ B_h^T P_{h+1,M} A_h & R_{h,M} + B_h^T P_{h+1,M} B_h \end{bmatrix} x.$$

This observation allows us to consider the following function approximation

$$F = (F_h)_{h\in[H+1]},$$

where each $F_h = \{x \mapsto x^T G_h x : G_h \in \mathbb{R}^{(d_a+d_u) \times (d_a+d_u)}\}$.

The quadratic function class satisfies Bellman realizability and completeness assumptions.

---

Note that LQR system often consider a cost function and the goal of the agent is to minimize the cumulative cost with $\bar{R}_{h,M}$ being semi-positive definite. We formulation this as a reward maximization problem for consistency. Thus, we consider $\bar{R}_{h,M} \prec 0$.  

22
Assumption 3 (Regularity parameters). Given the task set in Definition 8, we define some constants that appears on our bound. Let \( \pi^*_{t,h} \) be the optimal policy for \( M_{t,h} \). Let

\[
b_4 = \max_{i,h} \mathbb{E}_{\pi^*_{t,h}} \max_{h'} \| s_{h'} \|_2, \quad \text{and} \quad b_5 = \max_{i,h} \mathbb{E}_{\pi^*_{t,h}} \max_{h'} \| a_{h'} \|_2.
\]

These regularity assumption is reasonable because the optimal actions are linear transformations of states and we consider a finite-horizon MDP, with \( F_h^i \) having upper bounded eigenvalues.

Similarly to the linear MDP case, we assume that the system satisfies some visibility assumption.

Assumption 4 (Coverage Assumption). For any \( \nu \in \mathbb{R}^{d_s-1} \), there exists a policy \( \pi \) with \( \| a_{h} \|_2 \leq 1 \) such that

\[
\max \mathbb{E}_\pi \| s_{h+1} \nu \| \geq b_3, \quad \text{for} \quad b_3 > 1.
\]

Theorem 3. Given Assumption 3 and the diverse LQR task set in Definition 8, we have that for any \( f \in \mathcal{F}_\beta \) with \( \beta \leq (b_3^2 - 1)b_5^2/2 \),

\[
\alpha(f, \mathcal{F}, \mathcal{M}) = \Omega \left( \frac{\max \{ b_4^2, b_5^2 \} b_6^2}{d_s \lambda \max \{ (b_3^2 - 1)b_5^2, d_s \sigma^2 \} (b_3^2 - 1)b_5^2} \right).
\]

F.4 Proof of Theorem 3

Lemma 9. Assume that we have a set of policies \( \{ \pi_i \}_{i \in [d_s]} \) such that the \( i \)-th policy is a \( (b_3^2 - 1)b_5^2/2 \)-optimal policy for LQR with \( R_h^{i} = \epsilon_i e_i^T \) and \( R_h^{n} = -I \). Let \( \bar{\pi} = \text{Mixture}(\exp\{ \pi_i \}) \). Then we have

\[
\lambda_{\min} (\mathbb{E}_{\bar{\pi}} s_{h+1}s_{h+1}^T) \geq \frac{d_s \lambda \max \{ \Lambda, d_s \sigma^2 \}}{2 \max \{ b_4^2, b_5^2 \} \Pi_{h'=1}^{h-1} (1 - \epsilon_{h'}) e_{h'}}
\]

with \( \Lambda = (b_3^2 - 1)b_5^2 \).

Proof. We directly analyze the state covariance matrix at the step \( h + 1 \). Let \( \eta_h \sim \mathcal{N}(0, \sigma^2) \)

\[
\mathbb{E}_{\bar{\pi}} s_{h+1}s_{h+1}^T = \mathbb{E}_{\bar{\pi}} (A_h s_h + B_h \eta_h)(A_h s_h + B_h \eta_h)^T \geq \frac{d_s \lambda \max \{ \Lambda, d_s \sigma^2 \}}{2 \max \{ b_4^2, b_5^2 \} \Pi_{h'=1}^{h-1} (1 - \epsilon_{h'}) e_{h'}}
\]

(6)

To proceed, we show that \( \sum_{i=1}^{d_s} E_{\pi_i} s_h s_h^T \succeq \Lambda I \).

From Assumption 4, we have \( E_{\pi_i} s_h^T e_i e_i^T s_h - a_h a_h^T \succeq b_3^2 b_5^2 - b_5^2 \), and by the fact that \( \pi_i \) is a \( (b_3^2 - 1)b_5^2/2 \)-optimal policy, we have

\[
E_{\pi_i} s_h^T e_i e_i^T s_h - a_h a_h^T \succeq (b_3^2 b_5^2 - b_5^2)/2.
\]

Since \( E_{\pi_i} a_h a_h^T \succeq 0 \), we have \( E_{\pi_i} s_h^T e_i e_i^T s_h \succeq (b_3^2 - 1)b_5^2/2 \). Therefore, \( \sum_{i=1}^{d_s} E_{\pi_i} s_h s_h^T \succeq \Lambda I \) with \( \Lambda = (b_3^2 - 1)b_5^2/2 \).

Combined with (6), we have

\[
\mathbb{E}_{\pi} s_{h+1}s_{h+1}^T \succeq \frac{\Pi_{h'=1}^{h-1} (1 - \epsilon_{h'}) e_{h'}}{d_s} \left( \Lambda A_h A_h^T + d_s \sigma^2 B_h B_h^T \right).
\]

Apply Assumption 4 again, for each \( \nu_i = e_i, i = 1, \ldots, d_s \), there exists some policy \( \pi_i' \) with \( \| a_{h} \|_2 \leq b_5 \), such that \( \nu_i^T \mathbb{E}_{\pi_i'} s_{h+1}s_{h+1}^T \nu_i \succeq b_3^2 b_5^2 - b_5^2 \). Therefore, we have that \( \sum_{i=1}^{d_s} E_{\pi_i'} s_{h+1}s_{h+1}^T \succeq (b_3^2 - 1)b_5^2 \).
The proof is completed by
\[
\sum_{i=1}^{d_s} \mathbb{E}_{\pi'_i} s_{h+1} s_{h+1}^\top \leq 2 \sum_{i=1}^{d_s} \left( A_h \mathbb{E}_{\pi'_i} s_h s_h^\top A_h^\top + B_h \mathbb{E}_{\pi'_i} a_h a_h^\top B_h^\top \right) \\
\leq 2 \sum_{i=1}^{d_s} \left( b_h^2 A_h A_h^\top + b_h^2 B_h \mathbb{E}_{\pi'_i} B_h^\top \right) \\
\leq 2 \max \{ b_h^2, b_h^2 \} \prod_{h=1}^{h-1} (1 - \epsilon_h) \epsilon_h \mathbb{E}_\pi s_h s_{h+1} s_{h+1}^\top.
\]

To complete the proof of Theorem 3, we combine Lemma 10 and Lemma 9.

\[
F.5 \text{ SUPPORTING LEMMAS}
\]

Lemma 10 shows that having a full rank covariance matrix for the state \( s_h \) is a sufficient condition for bounded occupancy measure.

**Lemma 10.** Let \( \mathcal{F} \) be the function class described above. For any policy \( \pi \) and \( h \) such that
\[
\lambda_{\min}(\mathbb{E}_\pi [s_h s_h^\top]) \geq \lambda,
\]
we have for any \( \pi' \) such that \( \max_h \| s_h \|_2 \leq b_h \) and for any \( f' \in \mathcal{F} \),
\[
\mathbb{E}_{\pi'} \left[ (\mathcal{E}_h^2 f') (s_h, a_h) \right] \leq \frac{b_h^4}{\lambda^2} \mathbb{E}_\pi \left[ (\mathcal{E}_h^2 f') (s_h, a_h) \right].
\]

**Proof.** Lemma 11 shows that the Bellman error also takes a quadratic form of \( s_h \).

**Lemma 11.** For any \( f \in \mathcal{F} \), there exists some matrix \( \bar{G}_h \) such that \( (\mathcal{E}_h f)(x) = x^\top \bar{G}_h x \).

To complete the proof of Lemma 10, let \( w_h = s_h \otimes s_h \) be the Kronecker product between \( s_h \) and itself. By Lemma 11, we can write \( (\mathcal{E}_h f)(s_h) = \text{Vec}(\bar{G}_h)^\top w_h \). Again, this is an analog of the linear form we had for the linear MDP case. Thus, we can write \( (\mathcal{E}_h^2 f)(s_h) = \text{Vec}(\bar{G}_h)^\top w_h \text{Vec}(\bar{G}_h) \).

By Lemma 12 and the fact that \( \mathbb{E}_\pi (w_h w_h^\top) = \mathbb{E}_\pi (s_h s_h^\top) \otimes \mathbb{E}_\pi (s_h s_h^\top) \), we have \( \lambda_{\min}(\mathbb{E}_\pi w_h w_h^\top) \geq \lambda^2 \).

For any other policy \( \pi' \), and using the fact that \( \| w_h \| \leq b_h^2 \), we have
\[
\mathbb{E}_{\pi'} (\mathcal{E}_h^2 f)(s_h) = \mathbb{E}_{\pi'} [\text{Vec}(\bar{G}_h)^\top w_h w_h^\top \text{Vec}(\bar{G}_h)] \leq \frac{b_h^2}{\lambda^2} \mathbb{E}_{\pi} [\text{Vec}(\bar{G}_h)^\top w_h w_h^\top \text{Vec}(\bar{G}_h)] \leq \frac{b_h^2}{\lambda^2} \mathbb{E}_{\pi} (\mathcal{E}_h^2 f)(s_h).
\]

**Lemma 12.** For any \( f \in \mathcal{F} \), there exists some matrix \( \bar{G}_h \) such that \( (\mathcal{E}_h f)(x) = x^\top \bar{G}_h x \).

**Proof.** The Bellman error of the LQR can be written as
\[
(\mathcal{E}_h f)(x) = \left( x^\top \bar{G}_h x - s^\top R_h s - a^\top R_h a - \max_{a' \in \mathbb{R}^d_a} [(A_h s + B_h a)^\top, a'^\top] G_{h+1} \begin{bmatrix} A_h s + B_h a \\ a' \end{bmatrix} \right)
\]
Note that the optimal \( a' \) can be written as some linear transformation of \( x \). Thus we can write
\[
\max_{a' \in \mathbb{R}^d_a} [(A_h s + B_h a)^\top, a'^\top] G_{h+1} \begin{bmatrix} A_h s + B_h a \\ a' \end{bmatrix} = x^\top G' x.
\]

The whole equation can be written as a quadratic form as well.

**Lemma 12.** Let \( A \in \mathbb{R}^{d_x \times d_x} \) have eigenvalues \( \{\lambda_i\}_{i \in [d]} \) and \( B \in \mathbb{R}^{d_z \times d_z} \) have eigenvalues \( \{\mu_i\}_{i \in [d]} \). The eigenvalues of \( A \otimes B \) are \( \{\lambda_i \mu_j\}_{i \in [d], j \in [d]} \).
For any $\lambda$ MDMP, which case Assumption 5 guarantees that any $\beta$ (Lower bound on the largest achievable occupancy measure) is not a vacuous policy and it provides a lower bound on the corresponding occupancy measure. We will discuss later in Appendix G on how to remove this assumption with an extra $S \times H$ factor on the sample complexity bound.

**Proposition 5.** Consider a set of sparse reward MDP as in Definition 9. Assume Assumption 5 is true. For any $\beta \leq b_1/2$ and $f \in F_\beta$, we have $\alpha(f, F, M) \geq \bar{\alpha}$ for some constant $\bar{\alpha} = \sqrt{\beta^2/2e|M|A|H|}$ by choosing $\epsilon_0 = 1/h$.

**Proof.** We prove this lemma in a layered manner. Let $h'$ be the minimum step such that there exists some $M_{s,h'}$ is $\beta$-suboptimal. By definition, in the layer $h' - 1$, all the MDPs are $\beta$-suboptimal, in which case $\pi_{M_{s,h'-1}}$ visits $(s, h'-1)$ with a probability at least $b/2$. Now we show that the optimal policy $\pi^*_{M_{s,h'}}$ of a suboptimal MDP $M_{s,h'}$ has lower bounded occupancy ratio.

For a more concise notation, we let $M' = M_{s,h'}$. Note that

$$\mu_{h'}^\pi(s) = \sum_{s' \in S} \pi_{h'-1}^\pi(s') P_{h'-1}(s | s', \pi_M^*(s'))$$

$$\leq \sum_{s' \in S} \max_{\pi \in \Pi} \mu_{h'-1}^\pi(s') P_{h'-1}(s | s', \pi_M^*(s'))$$

(By the fact that $\pi_{M_{s',h'-1}}^\pi(s')$ is $\beta$-optimal policy of $M_{s',h'-1}$)

$$\leq \sum_{s' \in S} B_1 |M| A (1 - \epsilon)^{(h' - 1)\epsilon} \mu_{h'-1}^\pi(s') P_{h'-1}(s | s', \pi_M^*(s'))$$

$$= \frac{b_1 |M| A}{(1 - \epsilon)^{(h' - 1)\epsilon} \epsilon} \mu_{h'}^\pi(s)$$

The occupancy measure ratio can be upper bounded by $c = \frac{b_1 |M| A}{(1 - \epsilon)^{(h' - 1)\epsilon} \epsilon}$. Then the myopic exploration gap can be lower bounded by

$$\frac{\beta}{c} = \sqrt{(1 - \epsilon)^{(h' - 1)\epsilon} \epsilon} \geq \sqrt{\frac{\beta^2}{2 |M| A}}.$$
To proceed, we choose $\epsilon_h = 1/h$, which leads to $(1 - \epsilon_h)^{h-1}\epsilon \geq 1/(eH)$. \hfill $\square$

Plugging this into Theorem 1, we achieve a sample complexity bound of $O(S^2AH^5/\beta^2)$, with $|\mathcal{M}| = SH$. This is not a near-optimal bound for reward-free exploration (a fair comparison in our setup). This is because the sample complexity bound in Theorem 1 is not tailored for tabular case.

### G.2 Removing Coverage Assumption

Though Assumption 2 and Assumption 4 are relatively common in the literature, we have not seen an any like Assumption 5. In fact, Assumption 5 is not a necessary condition for sample-efficient myopic exploration as we will discuss in this section. The main technical invention is to construct a mirror transition probability that satisfies the conditions in Assumption 5. However, we will see that a inevitable price of an extra $SH$ factor has to be paid.

To illustrate the obstacle of removing Assumption 5, recall that the proof of Proposition 5 relies on the fact that all $\beta$-optimal policies guarantee a non-zero probability of visiting the state corresponding to their sparse reward with $\beta < b_1/2$. Without Assumption 5, a $\beta$-optimal policy can be an arbitrary policy. At the step $h$, we have at most $S$ such MDPs, which may accumulate an irreducible error of $S\beta$, which means that at the round $h + 1$, we can only guarantee $S\beta$-optimal policies. Any naive adaptation will require us to set the accuracy $\beta' = \beta/S^H$ in order to guarantee a $\beta$ error in the last step. The following discussion reveals that the error does not accumulate in a multiplicative way.

**Mirror MDP construction.** It is helpful to consider a mirror transition probability modified from our original transition probability. We denote the original transition probability by $P = \{P_h\}_{h \in [H]}$. Consider a new MDP with transition $P' = \{P'_h\}_{h \in [H]}$ and state space $S' = S \cup \{s_0\}$, where $s_0$ is a dummy state. We initialize $P'$ such that

$$P'_h(s' | s, a) = P_h(s' | s, a) \text{ for all } s', s, a, h, \text{ where } s' \neq s_0, \text{ and } P'_h(s_0 | s_0, \cdot) = 1 \quad (7)$$

Starting from $h = 1$, we update $P'_h$ by a forward induction according to Algorithm 2. The design principle is to direct the probability mass of visiting $(s, h+1)$ to $(s_0, h+1)$, whenever the maximal probability of visiting $(s, h+1)$ is less than $\beta$.

#### Algorithm 2 Creating Mirror Transitions

**Input:** Original Transition $P$, threshold $\beta > 0$.

Initialize $P'$ according to (7)

for $h = 1, 2, \ldots, H - 1$ do

\hspace{1cm} for each $s \in S$ such that $\max_{\pi} \mu^\pi_{h+1}(s) \leq \beta$ do

\hspace{1.5cm} $P'_h(s_0 | s, \bar{a}) \leftarrow P'_h(s_0 | s, \bar{a}) + P'_h(s | s, \bar{a})$ for each $\bar{s}, \bar{a}$.

\hspace{1cm} $P'_h(s | s, \bar{a}) \leftarrow 0$ for each $\bar{s}, \bar{a}$.

end for

end for

Return $P'$

By definition of $P'$, we have two nice properties.

**Proposition 6.** For any $h \in [H]$, $s \in S$, we have $\max_{\pi} \mu^\pi_{h}(s) = 0$ or $\max_{\pi} \mu^\pi_{h}(s) > \beta$.

Thus, $P'$ nicely satisfies our Assumption 5. We also have that $P'$ is not significantly different from $P$.

**Proposition 7.** For any policy $\pi$, $\mu^\pi_{h}(s) \geq \mu^\pi_{h}(s) - HS\beta$. Further more, any $(SH + 1)\beta$-suboptimal policy for $P$ is at least $\beta$-suboptimal for $P'$ with respect to the same reward.

**Proof.** We simply observe that $\max_{\pi} \mu^\pi_{h}(s_0) \leq (h - 1)S\beta$. This is true since at any round, we have at most $S$ states with $\max_{\pi} \mu^\pi_{\pi}(s) \leq \beta$, all the probability that goes to $s$ will be deviated to $s_0$. Therefore, for any $\pi$

$$\mu^\pi_{h+1}(s_0) \leq \mu^\pi_{h}(s_0) + S\beta.$$
Therefore, any \((SH + 1)\beta\)-suboptimal policy for \(P\) has the myopic exploration gap of \(\beta\)-suboptimal policy for \(P'\).

**Theorem 4.** Consider a set of sparse reward MDP as in Definition 9. For any \(\beta \in (0, 1)\) and \(f \in F_\beta\), we have \(\alpha(f, F, M) \geq \bar{\alpha}\) for some constant \(\bar{\alpha} = \Omega(\sqrt{r^2/|M|AS^2H^3})\) by choosing \(\epsilon_h = 1/(h + 1)\).

## H Connections to Diversity

Diversity has been an important consideration for the generalization performance of multitask learning. How to construct a diverse set, with which we can learn a model that generalizes to unseen task is studied in the literature of multitask supervised learning.

Previous works (Tripuraneni et al., 2020; Xu & Tewari, 2021) have studied the importance of diversity in multitask representation learning. They assume that the response variable is generated through mean function \(f_t \circ h\), where \(h\) is the representation function shared by different tasks and \(f_t\) is the task-specific prediction function of a task indexed by \(t\). They showed that diverse tasks can learn the shared representation that generalizes to unseen downstream tasks. More specifically, if \(f_t \in F\) is a discrete set, a diverse set needs to include all possible elements in \(F\). If \(F\) is the set of all bounded linear functions, we need \(d\) tasks to achieve a diverse set. Note that these results align with the results presented in the previous section. Could there be any connection between the diversity in multitask representation learning and the efficient myopic exploration?

[Xu & Tewari (2021)] showed that Eluder dimension is a measure for the hardness of being diverse. Here we introduce a generalized version called distributional Eluder dimension (Jin et al., 2021a).

**Definition 10** (\(\varepsilon\)-independence between distributions). Let \(G\) be a class of functions defined on a space \(X\), and \(\nu, \mu_1, \ldots, \mu_n\) be probability measures over \(X\). We say \(\nu\) is \(\varepsilon\)-independent of \(\{\mu_1, \mu_2, \ldots, \mu_n\}\) with respect to \(G\) if there exists \(g \in G\) such that \(\sqrt{\sum_{i=1}^{n} (E_{\mu_i}(g))^2} \leq \varepsilon\), but \(|E_{\nu}(g)| > \varepsilon\).

**Definition 11** (Distributional Eluder (DE) dimension). Let \(G\) be a function class defined on \(X\), and \(\Pi\) be a family of probability measures over \(X\). The distributional Eluder dimension \(\dim_{DE}(G, \Pi, \varepsilon)\) is the length of the longest sequence \(\{\rho_1, \ldots, \rho_n\} \subseteq \Pi\) such that there exists \(\varepsilon' \geq \varepsilon\) where each \(\rho_i\) is \(\varepsilon'\)-independent of \(\{\rho_1, \ldots, \rho_{i-1}\}\) for all \(i \in [n]\).

**Definition 12** (Bellman Eluder (BE) dimension (Jin et al., 2021)). Let \(E_h F\) be the set of Bellman residuals induced by \(F\) at step \(h\), and \(\Pi = \{\Pi_h\}_{h=1}^{H}\) be a collection of \(H\) probability measure families over \(X \times A\). The \(\varepsilon\)-Bellman Eluder dimension \(d_{BE}(F, \Pi, \varepsilon)\) of \(F\) with respect to \(\Pi\) is defined as:

\[
\dim_{BE}(F, \Pi, \varepsilon) := \max_{h \in [H]} \dim_{DE}(E_h F, \Pi, \varepsilon)
\]

**Constructing a diverse set.** For each \(h \in [H]\), consider a sequence of functions \(f_1, \ldots, f_d \in F\), such that the induced policy \((\pi^f_s)_{s \in [d]}\) generates probability measures \((\mu_{h+1}^s)_{s \in [d]}\) at the step \(h + 1\). Let \((\mu_{h+1}^s)_{s \in [d]}\) be \(\varepsilon\)-independence w.r.t the function class \(E_h F\) between their predecessors. By the definition of BE dimension, we can only find at most \(\dim_{DE}(E_h F, \Pi, \varepsilon)\) of these functions. Then conditions in Definition 12 is satisfied with \(c = 1/(dH)\).

**Revisiting linear MDPs.** The task set construction in 7 seems to be quite restricted as we require a set of standard basis. One might conjecture that a task set \(M_{h}, h\) with full rank \([\theta_{1,h}, \ldots, \theta_{d,h}]\) will suffice. From what we discussed in the general case, we will need the occupancy measure generated by the optimal policies for these MDPs to be \(\epsilon\)-independent and any other distribution is \(\epsilon\)-dependent. This is generally not true even if the reward parameters are full rank. To see this, let us consider a tabular MDP case with two states \{1, 2\}, where at the step \(h\), we have two tasks \(M_1, M_2\), with \(R_{h,M_1}(s, a) = 1[s = 1] + 0.49[s = 2]\) and \(R_{h,M_2}(s, a) = 0.511[s = 1] + 0.49[s = 2]\). This gives \(\theta_{h,M_1} = [1, 0]\) and \(\theta_{h,M_2} = [0.49, 0.51]\) as shown in Figure 3.

Construct the MDP such that the transition probability and action space any policy either visit state 1 or state 2 at the step \(h\). Then the optimal policies for both tasks are the same policy which visits state 1 with probability one, even if the reward parameters \([\theta_{h,M_1}, \theta_{h,M_2}]\) are full-rank.
Figure 3: An illustration of why a full-rank set of reward parameters does not achieve diversity. The red arrows are two reward parameters and the star marks the generated state distributions of the optimal policies corresponding to the two rewards at the step $h$. Since both optimal policies only visit state 1, they may not provide a sufficient exploration for the next time step $h + 1$.

I IMPLICATIONS OF DIVERSITY ON ROBOTIC CONTROL ENVIRONMENTS

In this section, we conduct simulation studies on robotic control environments with practical interests. Since myopic exploration has been shown empirically efficient in many problems of interest, we focus on the other main topic–diversity. We investigate how our theory guides a diverse task set selection. More specifically, our prior analysis on Linear MDPs suggests that a diverse task set should prioritize tasks with full-rank feature covariance matrices. We ask whether tasks with a more spread spectrum of the feature covariance matrix lead to a better training task set. Note that the goal of this experiment is not to show the practical interests of Algorithm 1. Instead, we are revealing interesting implications of the highly conceptual definition of diversity in problems with practical interests.

Environment and training setup. We adopt the BipedalWalker environment from (Portelas et al., 2020). The learning agent is embodied into a bipedal walker whose motors are controllable with torque (i.e. continuous action space). The observation space consists of laser scan, head position, and joint positions. The objective of the agent is to move forward as far as possible, while crossing stumps with varying heights at regular intervals (see Figure 4 (a)). The agent receives positive rewards for moving forward and negative rewards for torque usage. An environment or task, denoted as $M_{p,q}$, is controlled by a parameter vector $(p, q)$, where $p$ and $q$ denote the heights of the stumps and the spacings between the stumps, respectively. Intuitively, an environment with higher and denser stumps is more challenging to solve. We set the parameter ranges for $p$ and $q$ as $p \in [0, 3]$ and $q \in [0, 6]$ in this study.

The agent is trained by Proximal Policy Optimization (PPO) (Schulman et al., 2017) with a standard actor-critic framework (Konda & Tsitsiklis, 1999) and with Boltzmann exploration that regularizes entropy. Note that Boltzmann exploration strategy is another example of myopic exploration, which is commonly used for continuous action space. Though it deviates from the $\epsilon$-greedy strategy discussed in the theoretical framework, we remark that the theoretical guarantee outlined in this paper can be trivially extend to Boltzmann exploration. The architecture for the actor and critic extractors consists of two layers with 400 and 300 neurons, respectively, and Tanh (Rumelhart et al., 1986) as the activation function. Fully-connected layers are then used to compute the action and value. We keep the hyper-parameters for training the agent the same as Romac et al. (2021).

I.1 INVESTIGATING FEATURE COVARIANCE MATRIX

We denote by $\phi(s, a)$ the output of the feature extractor. We evaluate the extracted feature at the end of the training generated by near-optimal policies, denoted as $\pi$, on 100 tasks with different parameter vectors $(p, q)$. We then compute the covariance matrix of the features for each task, denoted as $V_{p,q} = \mathbb{E}_{\pi}^{M_{p,q}} \sum_{h=1}^{H} \phi(s_h, a_h)\phi(s_h, a_h)^T$, whose spectrums are shown in Figure 4 (b) and (c).

By ignoring the extremely large and small eigenvalues on two ends, we focus on the largest 100-200 dimension, where we observe that the height of the stumps $p$ has a larger impact on the distribution of eigenvalues. In Figure 4 (b), we show the boxplot of the log-scaled eigenvalues of 100-200 dimensions for environments with different heights, where we average spacings. We observe that the eigenvalues can be 10 times higher for environments with an appropriate height (1.0-2.3), compared
to extremely high and low heights. However, the scales of eigenvalues are roughly the same if we control the spacings and take average over different heights as shown in Figure 4 (c). This indicates that choosing an appropriate height is the key to properly scheduling tasks.

In fact, the task selection coincides with the tasks selected by the state-of-the-art Automatic Curriculum Learning (ACL). We investigate the curricula generated by ALP-GMM (Portelas et al., 2020), a well-established curriculum learning algorithm, for training an agent in the BipedalWalker environment for 20 million timesteps. Figure 4 (d) gives the density plots of the ACL task sampler during the training process, which shows a significant preference over heights in the middle range, with little preference over spacing.

Figure 4: (a) BipedalWalker Environment with different stump spacing and heights. (b-c) Boxplots of the log-scaled eigenvalues of sample covariance matrices of the trained embeddings generated by the near optimal policies for different environments. In (b), we take average over environments with the same height while in (c), over the same spacing. (d) Task preference of automatically generated curriculum at 5M and 10M training steps respectively. The red regions are the regions where a task has a higher probability to be sampled.

Training on different parameters. To further validate our finding, we train the same PPO agent with different means of the stump heights and see that how many tasks does the current agent master. As we argued in the theory, a diverse set of tasks provides good behavior policies for other tasks of interest. Therefore, we also test how many tasks it could further master if one use the current policy as behavior policy for fine-tuning on all tasks. The number of tasks the agent can master by learning on environments with heights ranging in [0.0, 0.3], [1.3, 1.6], [2.6, 3.0] are 28.1, 41.6, 11.5, respectively leading to a significant outperforming for diverse tasks ranging in [1.3, 1.6]. Table 1 gives a complete summary of the results.

Table 1: Training on different environment parameters. Each row represents a training scenario, where the first two columns are the range of sampled parameters. The mastered tasks are out of 121 evaluated tasks with the standard deviation calculated from ten independent runs.
